CHAPTER

29

# SMALLPOX AND VACCINIA

**Julia A. McMillan**

## CHAPTER OUTLINE

Smallpox is a severe exanthematous clinical disease caused by variola virus. Variola is a member of the genus *Orthopoxvirus* in the Poxviridae family; this genus also includes monkeypox, cowpox, rabbitpox, and vaccinia. Variola infection occurs only in humans, a fact that allowed eradication of this infection in the latter part of the 20th century in a global eradication program using preventive vaccine derived from the relatively benign vaccinia virus. The last case of smallpox in the United States occurred in 1949. In 1980, the world was declared free of smallpox by the World Health Organization (WHO); the last endemic case was diagnosed in Somalia in 1977. Routine vaccination of children and the general public was discontinued in the United States in 1972, and vaccination of health care workers was discontinued in 1976.

The U.S. Public Health Service accepted the recommendation of the Advisory Committee on Immunization Practices that routine smallpox vaccination in the United States be discontinued in 1971. This recommendation was based on two considerations: (1) the risk of contracting smallpox in the United States was small and (2) the risk of complications from immunization with vaccinia outweighed the potential benefits [1].

In 1986, international agreement led to destruction of all variola isolates except stocks to be maintained in WHO-designated laboratories in the United States and the Soviet Union. Concern that variola might be used as an agent of bioterrorism was raised during the 1990s, when it was learned that variola stored in the former Soviet Union had been sold to countries thought to be developing biologic weapons. It is in this context that smallpox and vaccinia virus and their potential effects on the pregnant woman and fetus have again become a matter of potential concern.

## EPIDEMIOLOGY AND TRANSMISSION

### VARIOLA

Variola was spread primarily through respiratory secretions in aerosolized droplets, and secondary infection required prolonged (6 to 7 hours) face-to-face contact. Infection through direct contact with infected lesions, bedding, or clothing was thought to occur infrequently. The incubation period was 7 to 17 days (mean 12 days). Infected individuals were not generally contagious until the rash appeared after a 3- to 4-day prodrome of fever, malaise, backache, vomiting, and prostration. Because of the severity of the prodromal illness, infected individuals were usually confined to home or hospital by the time they presented a risk to others, and household contacts and health care professionals were the most frequent secondary cases. Infectivity persisted until all scabs had separated from the skin of the affected individual. The likelihood of spread to a susceptible individual was considered to be lower than that for measles and similar to the rate for varicella. Low temperature and dry conditions prolong virus survival, and outbreaks in the past were more common during dry winter months.

Past recorded experience regarding the frequency of transmission of variola from mother to fetus must be considered against the backdrop of near-universal childhood vaccination. Infection during the first half of gestation resulted in an increased likelihood of fetal death or prematurity. Overall, the rate of fetal loss or death after premature delivery ranged from 57% to 81% [2,3]. There are some documented cases of live-born infants infected in utero near term. In those instances, the likelihood of congenital or neonatal infection was greatest when the mother became ill during the period from 4 days before delivery to 9 days after delivery [4,5].

### VACCINIA

Vaccinia virus transmission to the fetus after vaccination of pregnant women has been documented [6–8], although the frequency with which it occurs and the severity of resulting disease are difficult to determine from studies published during past decades [9,10]. Surveys that attempted to determine the rate of adverse effects of smallpox vaccination in the United States during the 20th century identified only one case of fetal vaccinia. In a retrospective study in

DOI: 10.1016/B978-1-4160-6400-8.00029-8

Scotland that depended on maternal recollection of timing of vaccination, MacArthur [6] found that fetal death occurred in 47% of pregnancies involving women vaccinated during the second or third trimesters and 24% of those vaccinated during the first trimester. Other studies have failed to find an increased risk of fetal death, miscarriage, or fetal malformations [11,12]. Primary vaccination during pregnancy in the years in which these studies were conducted was unusual, however, and the potential impact on the fetus after vaccination of nonimmune pregnant women cannot be extrapolated accurately.

For almost 30 years (1976–2002), vaccination against smallpox was available in the United States only for scientists who worked with vaccinia and related viruses in the laboratory setting. In 2002, the U.S. Department of Defense initiated a pre-event vaccination program to protect its personnel, and in 2003, the U.S. Public Health Service began vaccinating health care and public health workers who might be involved in caring for patients with smallpox or investigating circumstances surrounding the use of smallpox as an agent of bioterrorism. Criteria for exclusion of individuals at risk for adverse events (including pregnant women) were developed. Despite careful screening, military records indicate that during the calendar years 2003 and 2004, 7735 infants were born to women who inadvertently received smallpox vaccine (vaccinia) at some time during their pregnancy. Review of pregnancy outcomes for these women compared with military women who were pregnant during that same period and did not receive smallpox vaccine showed no statistically significant differences in frequency of birth defects or preterm delivery. When the comparison was limited to mothers who received vaccine during the first trimester, there was a small increase in the odds ratio for overall birth defects, but that finding also was not statistically significant [13].

In early 2003 the National Smallpox Vaccine in Pregnancy Registry was established by the U.S. Department of Defense and the Centers for Disease Control and Prevention (CDC) to enroll and follow prospectively women who had been inadvertently vaccinated while pregnant or within 4 weeks of conception as a part of the military or civilian public health preparedness effort. As of September 2006, 376 women had enrolled in the registry; 354 (94.1%) of these women had never received smallpox vaccine in the past. Most of the women in the registry (76.9%) were vaccinated during the first 4 weeks of pregnancy. There have been no cases of fetal vaccinia and no increase in fetal loss, prematurity, low birth weight, or major anomalies compared with the expected rates in the U.S. population [14]. Although these more recent studies offer reassurance that smallpox vaccination during pregnancy does not have adverse consequences for the fetus, caution must be used in extrapolating these results to a larger population whose overall health may be more variable.

## MICROBIOLOGY

The poxviruses, including variola and vaccinia, are large, complex, double-stranded DNA viruses with a diameter of approximately 200 nm. The nucleotides of the two viruses are 96% homologous, as are 93% of the amino acids of the glycoproteins that make up the envelope of the two viruses. These envelope glycoproteins are important in antibody recognition. The virions have a characteristic brick shape on electron microscopy. Viral aggregates in infected host cells form intracytoplasmic inclusion bodies of approximately 10 μm. Both viruses can be grown on tissue culture derived from various mammalian cells, and cytopathic changes can be detected within 1 to 6 days.

## PATHOGENESIS, PATHOLOGY, AND PROGNOSIS

### VARIOLA

Introduction of variola onto respiratory mucosa is followed by local multiplication and spread to lymph nodes. An asymptomatic viremia occurs on about the 3rd or 4th day, distributing the virus to the spleen, bone marrow, and lymph nodes. Secondary viremia, occurring on about day 8, is followed on day 12 to 14 by systemic symptoms, including fever, malaise, headache, and prostration. During this secondary viremia, virus is carried by leukocytes to the dermis and oropharyngeal mucosa. Prodromal febrile illness is followed after about 3 days by development of enanthem and a maculopapular rash distributed at first primarily on the face, arms, and legs and then spreading to the trunk.

Mortality rates after smallpox varied depending on age, prior vaccination, and availability of supportive care. To some degree, mortality can be predicted by the characteristics of the rash (see "Clinical Manifestations"). Overall, the mortality rate was about 30%.

The mortality rate from smallpox among pregnant women was high. The more lethal hemorrhagic form of smallpox was more likely to occur in pregnant women. Rao and colleagues [3] followed 225 pregnant women in India from 1959–1962 and found a 75% mortality rate among previously unvaccinated pregnant women who developed smallpox compared with 24% to 25% among unvaccinated nonpregnant women and men. For vaccinated women, the mortality rate was 20.7% compared with 3% to 4% for men and nonpregnant women. Dixon [15] reported an overall mortality rate of 40% among pregnant women in a smallpox outbreak in North Africa in 1946.

Even when maternal infection is mild, transmission to the fetus can lead to increased rates of fetal death and premature delivery. Among 46 pregnancies followed by Lynch [2], 81% resulted in fetal death or early death after premature delivery. Other investigators reported much less frequent adverse effects on the fetus [4]. The sequence of events that lead to infection of the placenta and fetus in relation to maternal viremia has not been conclusively established. Development of symptomatic infection at 2 to 3 weeks of life in infants born to mothers whose illness began just before delivery suggests that placental infection and transmission to the fetus developed during the secondary viremic phase [4,11]. The consequences of fetal infection have been documented to involve widely disseminated foci of necrosis (i.e., skin, thymus, lungs, liver, kidneys, intestines, and adrenals) and characteristic intracytoplasmic inclusion bodies (i.e., Guarnieri bodies) in the decidual cells of the placenta [16,17].

It is thought that transplacental transmission of variola can occur at any time during gestation, and autopsy studies corroborate infection acquired during the second and third trimesters. Pathologic studies of fetuses lost during the first trimester are lacking; however, the increased frequency of miscarriage associated with maternal infection at that stage suggests a direct effect on the products of conception.

## VACCINIA

Vaccinia infection after maternal vaccination is thought to result from transient viremia. The frequency with which inoculation of vaccinia virus through vaccination leads to viremia probably is related to the invasiveness of the vaccinia strain and the vaccination status (i.e., primary versus revaccination) of the individual being vaccinated. A report involving persons vaccinated from 1930–1953 described isolation of vaccinia 3 to 10 days after vaccination with a strain that is thought to be more invasive than the New York City Board of Health (NYCBOH) strain used during recent decades [18]. Viremia has been reported after NYCBOH strain vaccination [18,19], but the frequency with which it occurs is unknown. A study involving 28 healthy adults vaccinated using NYCBOH vaccine failed to detect viremia after successful vaccination [20]. Mihailescu and Petrovici [21] were able to isolate vaccinia from products of conception of 12 (3.2%) of 366 women who had been revaccinated during pregnancy and had undergone therapeutic abortion during the 1st or 2nd month of gestation.

In the past, pregnancy was not considered a contraindication to vaccination during periods of increased smallpox risk, and despite widespread use of vaccine during the past century, only 50 cases of fetal infection (3 in the United States) have been reported [22]. Levine and coworkers [23] summarized 20 cases of fetal vaccinia infection reported from 1932–1972. At least 13 of the 20 women involved had received their first smallpox vaccination during the pregnancy. The time of vaccination ranged from 3 to 24 weeks of pregnancy, and delivery occurred an average of 8 weeks later; 10 infected infants were born alive, and 3 survived (Figs. 29–1 and 29–2).

# CLINICAL MANIFESTATIONS

## VARIOLA

Variola major is the form of smallpox that is of the greatest historical significance because of its high overall mortality rate (30%). Onset of rash was preceded by approximately 3 days of fever, myalgia, headache, and backache. Vomiting, diarrhea, abdominal pain, and seizures sometimes accompanied this prodromal period. The fever often was reduced as the rash appeared, only to recur and persist until skin lesions had scabbed. The appearance of the rash in patients with variola major was predictive of the severity of illness and of the associated mortality. The most common rash (90% of patients) was called *ordinary smallpox* and consisted of papules that progressed first to fluid-filled vesicles and then to firm, tense pustules that scabbed after 10 days to 2 weeks before separating from the underlying skin. The "pox" were distributed over the entire body, but predominated on the face and extremities, including the palms and soles. In contrast to the lesions of varicella, which appear in various stages (e.g., papules, vesicles, scabs) at one time, smallpox lesions all develop at the same rate. An enanthem involving painful lesions of the mouth and throat preceded the development of the rash by a day or less.

When the rash involved discrete lesions, it was referred to as *ordinary-discrete smallpox*. The case-fatality rate

**FIGURE 29–1 Generalized fetal vaccinia in an infant whose mother was immunized at 24 weeks of gestation.** The infant was born at 30 weeks and survived. *(From Hanshaw JC, Dudgeon JA. Viral Diseases of the Fetus and Newborn. Philadelphia, Saunders, 1978, p 216.)*

**FIGURE 29–2 The same patient as in Figure 29–1 at 18 months of age.** Scarring persists, but the lesions have healed. Smallpox vaccination was attempted without success. *(From Hanshaw JC, Dudgeon JA. Viral Diseases of the Fetus and Newborn. Philadelphia, Saunders, 1978, p 217.)*

associated with this form was less than 10%. When lesions were more numerous and less discrete (i.e., ordinary-semiconfluent and ordinary-confluent smallpox), the mortality rate was higher, approximating 50% to 75% for ordinary-confluent cases. Flat smallpox, in which lesions evolved more slowly and finally coalesced, accounted for about 7% of cases, but the mortality rate was greater than 90%. Hemorrhagic smallpox, or purpura variolosa, which was seen most commonly in pregnant women, was associated with an almost 100% mortality rate [24]. In the series of 255 pregnant women reported by Rao and colleagues [3], smallpox was least likely to take the hemorrhagic form during the first trimester of pregnancy, and the highest likelihood of the hemorrhagic form was during the 6th month. Modified smallpox, affecting previously vaccinated individuals, was a milder disease with fewer and smaller skin lesions. Death with this form was rare.

Alastrim, or variola minor, is virologically distinct from variola major. It was first recognized in the early 20th century in South Africa, spreading to the Americas and to Europe. As the name suggests, this form of smallpox was less severe, with a case-fatality rate of about 1%.

The increased likelihood of fetal death associated with maternal infection during pregnancy was described previously. When pathologic examination of the fetus and placenta in such cases has been reported, the fetus has exhibited well-circumscribed cutaneous and scalp lesions with maceration of internal organs, including the brain. Foci of necrosis and calcification have been seen in the thymus, lungs, liver, kidneys, intestines, and adrenals. Similar foci are seen in the placenta [16,17].

Marsden and Greenfield [4] described 34 infants whose mothers developed smallpox late in pregnancy or during the 2 weeks after delivery. Some newborns escaped symptomatic illness, although failed attempts at subsequent vaccination suggest that they were infected in utero. Based on the timing of illness in the newborns who developed smallpox compared with the appearance of rash in the mother, these investigators concluded that transmission of virus from mother to fetus occurs during the expected time of secondary maternal viremia. Other reports substantiate their conclusions. These and other researchers [2,15] describe great variability in severity of neonatal illness, including instances in which one twin escaped clinical disease, but the other developed smallpox [15].

The severity of fetal or neonatal involvement does not reflect the severity of maternal infection or her vaccination status. In his report of 47 cases of maternal-to-fetal transmission of variola, Lynch [2] described five infected infants born at term whose mothers had been exposed to smallpox during pregnancy, but had escaped clinical disease, presumably because of prior vaccination. Vaccination of newborns whose mothers developed clinical smallpox before or shortly after their birth did not always protect them from disease.

Details regarding the clinical findings and course associated with congenital variola are unavailable. Disease was acute and not associated with congenital anomalies. Some reports describe cutaneous lesions that are larger than the lesions usually associated with smallpox. Among the 22 infants with congenital and neonatal smallpox described by Marsden and Greenfield [4], 3 died, 1 of whom was born prematurely.

## VACCINIA

Congenital vaccinia was rare, even during widespread vaccination programs. Reported mortality rate associated with congenital vaccinia was high, however. Of the 16 cases reviewed by Green and coworkers [8], six infants were born alive, but only one ultimately survived.

For at least 12 of the 16 women, vaccination during pregnancy had been their primary smallpox vaccination. Congenital vaccinia has been reported after vaccination between the 3rd and 24th weeks of pregnancy, but for most affected pregnancies, vaccination was in the second trimester. As is the case with congenital variola, large, discrete, circular necrotic lesions were seen on the skin of infected fetuses and newborns. Foci of necrosis studded multiple internal organs and the placenta.

In utero vaccinia infection has not been associated with serious birth defects or with other long-term adverse events in surviving infants. Infants of mothers vaccinated during pregnancy who escaped fetal infection were not at risk for sequelae.

**TABLE 29–1** Clinical Features Distinguishing Chickenpox from Smallpox

| Clinical Features | Chickenpox | Smallpox |
|---|---|---|
| Fever onset | At the time of rash | 2–4 days before rash |
| Rash characteristics | Pocks in different stages | Pocks in same stages |
| | Develops rapidly | Develops slowly |
| | More pocks on body | More pocks on face, arms, and legs |
| | Spares palms and soles | Affects palms and soles |
| Mortality | Rare | 10%–30%, historically |

## DIAGNOSIS

Diagnosis of smallpox, whether in the pregnant woman, fetus, or newborn, was usually based on clinical findings along with a history of exposure to disease or vaccination. Today, suspicion that a patient may have smallpox would imply introduction of the disease through bioterrorism, and great care should be taken to prevent spread of the infection and to confirm the diagnosis in the laboratory. If skin lesions are scabbed, one or more scabs should be removed and included with other specimens. Local and state health authorities should be contacted immediately. State authorities should contact the CDC. Patient samples should be collected only by an individual wearing protective gown, mask, and gloves, and that individual should be someone who has been vaccinated, if possible. Throat swabs and swabs of vesicular fluid should be obtained. Blood samples and the swabs should be placed into a container sealed with adhesive tape and then placed into a second, watertight container. All samples should be sent directly to a Biological Safety Level 4 laboratory, where they can be processed safely. Laboratory confirmation can be performed by electron microscopy, nucleic acid identification, immunohistochemical studies, and tissue culture using cell culture or chorioallantoic egg membrane. Similar technique should be employed to confirm infection in the neonate. There is no known reliable intrauterine test for diagnosing congenital infection.

## DIFFERENTIAL DIAGNOSIS

During the prodromal period, before the eruption of rash, maternal smallpox may be indistinguishable from other acute febrile illnesses. When the rash appears, the pattern of eruption and the characteristics of individual pox lesions should help distinguish it from other conditions, such as rubella, measles, meningococcemia, rickettsial diseases, rat-bite fever, and enteroviral infections. The widespread distribution of the lesions of variola major should distinguish it from localized papulovesicular rashes, such as impetigo, shingles, and insect bites. Varicella is the viral infection most likely to be confused with smallpox. Recommended routine vaccination of children against varicella leaves many younger clinicians without experience in recognizing this formerly common infection of childhood. Table 29–1 compares clinical characteristics of the two infections. In the past, smallpox sometimes was mistaken for drug eruptions and erythema multiforme, and hemorrhagic smallpox could be difficult to distinguish from meningococcemia, severe acute leukemia, or hemorrhagic varicella.

Congenital variola or vaccinia would be expected only in the context of a history of maternal smallpox or smallpox vaccination. In addition to careful consideration of prenatal maternal history, review of maternal postpartum course is important because historical reports suggest that neonatal smallpox may occur in association with maternal disease that manifests in the days after delivery [3]. In the absence of a maternal history of smallpox or vaccination, fetal or neonatal variola or vaccinia could be mistaken for congenital herpes simplex infection, congenital syphilis, or congenital dermatologic disease such as epidermolysis bullosa.

## TREATMENT

### VARIOLA

If maternal smallpox is suspected, contact and airborne isolation precautions, in addition to universal precautions, should be instituted immediately, and the patient should be cared for in a negative-pressure room if possible. Local and state health authorities should be notified immediately. Family and community contacts, emergency medical personnel, and health care workers who might have been exposed to the patient should be identified and immunized as soon as possible. Immunization within 4 days can ameliorate illness and, in some cases, prevent infection completely.

Patient management includes careful attention to fluid and electrolyte requirements and nutritional support. Antibiotic therapy, including an agent effective in treating infection caused by *Staphylococcus aureus*, should be provided if secondary infection is suspected. Cidofovir, a nucleoside analogue that inhibits DNA polymerase, has activity against variola. When used early in the course of infection, it has been effective in treating poxvirus infections in animals. Cidofovir is approved for use in treating cytomegalovirus infection, but it has not been used to treat smallpox. Adverse effects of cidofovir, primarily renal toxicity, would limit its use in treating suspected congenital variola.

## VACCINIA

Adverse effects associated with administration of smallpox vaccine include inadvertent inoculation of sites beyond the vaccination site, including ocular inoculation, generalized vaccinia, eczema vaccinatum, progressive vaccinia (i.e., vaccinia necrosum), postvaccinal encephalitis, and fetal vaccinia. Vaccination programs have developed careful screening tools to prevent vaccination of individuals thought to be particularly susceptible to these adverse effects, including exclusion of women who are pregnant or intend to become pregnant within 4 weeks of vaccination. Congenital vaccinia among live-born infants is rare, and inadvertent vaccination during pregnancy should not be a reason to recommend termination of pregnancy. Vaccinia immunoglobulin (VIG) has been used to treat some complications associated with smallpox vaccination, including eczema vaccinatum and progressive vaccinia. It may be used for those same reasons during pregnancy, but VIG is not recommended as prophylaxis against congenital vaccinia. No data are available regarding appropriate dose or efficacy of VIG for treatment of congenital vaccinia. Treatment may be considered, however, for a viable infant born with lesions after a history of maternal vaccination. For information concerning availability, indications, and administration of VIG, physicians should contact the CDC Clinical Consultation Team (telephone: 877-554-4625).

Cidofovir is available for treatment of complications of smallpox vaccination only under the investigational new drug (IND) protocol administered by the CDC. It is released only as secondary treatment for complications that do not respond to treatment with VIG. An investigational agent, ST-246, was used more recently, along with VIG and cidofovir, to treat a 28-month-old boy who developed eczema vaccinatum after contact with his father, who had received smallpox vaccine 21 days before visiting his family while on leave from Iraq [25]. ST-246 has in vitro activity against multiple orthopoxviruses, and no serious adverse reactions were seen in human phase I studies. The combined treatment was successful in this single case, but the role of any single one of the three therapies could not be determined.

## PREVENTION

After a remarkable, worldwide public health effort, smallpox was the first infectious disease to be eradicated in nature, during the latter part of the 20th century. Until concerns were raised regarding the potential use of smallpox as an agent of bioterrorism, protection from smallpox was thought to be unnecessary, and vaccination to protect against variola was discontinued. In the 21st century, inadvertent vaccination of pregnant military personnel, health care workers, and public health workers, many of whom are being vaccinated for the first time, poses the greatest risk for maternal and fetal infection. Careful screening of such individuals has been shown generally to be effective, but vaccination during pregnancy has occurred despite screening.

The National Smallpox Vaccine in Pregnancy Registry has been established to investigate instances of inadvertent smallpox vaccination during pregnancy. Civilian cases should be reported to state health departments or to the CDC (telephone: 404-639-8253 or 877-554-4625). Military cases should be reported to the Department of Defense (telephone: 619-553-9255; DSN: 619-553-9255; fax: 619-553-7601; e-mail: code25@nhrc.navy.mil). Health care providers are encouraged to save and forward products of conception from pregnancy losses associated with vaccination during pregnancy to the CDC or the Department of Defense. Specimens should be frozen at −70° C, preferably in viral transport media before and during transport.

In September 2007, ACAM2000 replaced Dryvax as the only smallpox vaccine licensed by the U.S. Food and Drug Administration (FDA). Similar to Dryvax, which was initially approved in 1931, ACAM2000 is a live vaccinia virus vaccine; in contrast to Dryvax, ACAM2000 is produced in cell culture, allowing more rapid and uniform large scale production (*FDA News*) [26].

CHAPTER

30

# LESS COMMON VIRAL INFECTIONS

**Yvonne A. Maldonado**

CHAPTER OUTLINE

## HUMAN PAPILLOMAVIRUS

Human papillomaviruses (HPV) are the cause of condyloma acuminatum (i.e., genital warts), cervical condylomata and cervical cancer [1–4]. More than 100 human HPV serotypes have been identified; approximately half of these have a predilection for anogenital infection [5,6]. Of these, serotypes 6 and 11 account for greater than 70% of cervical cancer worldwide, and serotypes 16 and 18 account for greater than 90% of anogenital warts [7,8]. The risk to an infant born to a mother with HPV infection is the development of juvenile laryngeal papillomatosis and possible development of anogenital warts, primarily owing to HPV serotypes 6 and 11 [9,10].

Hajek [11] associated the presence of condyloma acuminatum in a mother at the time of delivery with the subsequent development of laryngeal papilloma in her infant (Table 30–1). Cook and colleagues [12] described a similar association in five of nine children with laryngeal papilloma. All five of the children who developed laryngeal papilloma when younger than 6 months old were born to mothers who had condylomata acuminata at the time of delivery. The mothers of two of four other children with laryngeal papilloma had genital warts, but did not have them at the time of delivery. Seven (78%) of the nine children with laryngeal papilloma had mothers with condylomata acuminata. The expected incidence of condylomata acuminata in women in the population studied by Cook and colleagues [12] was 1.5%. Six of the nine children also had skin warts. Quick and coworkers [13] described a strong association between laryngeal papilloma in young children and maternal condylomata. Of the 31 patients with laryngeal papilloma they studied, 21 (68%) had been born to mothers who had had condylomata.

The basis for this epidemiologic relationship is evident from the detection of HPV DNA sequences in genital and laryngeal papilloma tissues [3]. Numerous studies have reported rates of newborn infection that ranged from 4% to 72% among infants born to HPV-infected mothers and 0.6% to 20% among infants born to mothers without detectable HPV DNA [14–20]. Smith and colleagues [21] investigated the risk of perinatal transmission based on concordance and sequence match to HPV types of both parents. Only 9 (1.6%) of 574 oral or genital specimens from newborns were positive for HPV DNA, and of those, only one maternal-infant HPV match was detected, suggesting that perinatal transmission is rare [21]. Rare associations have been made between maternal genital HPV infections and neonatal giant cell hepatitis [22] and vulvar genital papillomas among stillborns [23]. Both associations were documented in only a few gestations, but were confirmed by HPV DNA polymerase chain reaction (PCR) or by electron microscopy.

HPV cannot be isolated by means of tissue culture, but HPV DNA sequences can be detected in cervical cells. Cervical infection is caused by several types of HPV, including types 6, 11, 16, 18, and 31, and is highly prevalent worldwide. HPV can be detected in epithelial cells that have a normal histologic appearance and from tissue samples of patients whose papillomatous lesions are in remission [24]. Clinically, most genital HPV infection is asymptomatic. The frequency of HPV detection has ranged from 5% to 15% in studies of women of childbearing age, with the highest incidence occurring among younger women [25–28]. Pregnancy was not associated with a higher rate of infection.

Although the incidence of cervical infection was 20% in women with a history of condyloma, most pregnant women with HPV infection do not have a history of genital warts. Infection of the infant probably occurs by exposure to the virus at delivery, although papillomatosis has been described in infants delivered by cesarean section. Tang and associates [29] described an infant who was born with condylomata acuminata around the anal orifice. The mother also had condylomata acuminata. It is unknown whether this case reflects transplacental hematogenous spread or direct extension across intact membranes.

Despite the prevalence of genital HPV infection, juvenile laryngeal papillomatosis remains a rare disease. The incidence of recurrent respiratory papillomatosis is approximately 3.96 per 100,000 in the pediatric population, with an incidence of 7 of every 1000 infants born to mothers with vaginal condyloma. The risk of subclinical transmission of HPV from mothers to infants is unknown. HPV-6 and HPV-16 DNA sequences were detected in the cells from foreskin tissue of 3 of 70 infants [30]. These HPV types are also found in genital warts. Because of the

**TABLE 30–1** Effects of Other Viral Infections of the Fetus and Newborn

| Infectious Agent | Increased Incidence of Abortion | Increased Risk of Prematurity | Major Clinical Manifestations in Infants |
|---|---|---|---|
| Human papillomavirus | No | No | Laryngeal papilloma, anogenital warts |
| Epstein-Barr virus | Possibly | Possibly | Unknown |
| Human herpesvirus 6 | No | No | Febrile illness in postnatal period |
| Influenza viruses | No | No | Probably none |
| Respiratory syncytial virus | No | No | Pneumonia, bronchiolitis in postnatal period |
| Lymphocytic choriomeningitis virus | Yes | No | Hydrocephalus, chorioretinitis, viral meningitis, jaundice, thrombocytopenia (?) |
| Molluscum contagiosum virus | No | No | Rash |
| Rabies | No | No | None known |

prevalence of asymptomatic HPV infection, the feasibility of preventing the rare cases of laryngeal papillomatosis by considering maternal condyloma acuminatum as an indication for cesarean delivery is uncertain.

Treatment of anogenital warts is not optimal, but podophyllum resin or podofilox is often used in older children and adults. Neither podophyllum resin nor podofilox has been tested for safety or efficacy in children, and both agents are contraindicated for use in pregnancy. Laryngeal papillomas recur even after repeated surgical removal. Interferon has been used with some success for treatment of laryngeal papillomas [31]. Although the mainstay of surgical management has traditionally been the $CO_2$ laser, newer surgical techniques have shown efficacy in the management of pediatric patients, including powered instrumentation and the pulsed dye laser. The traditional adjuvant medical therapies used for pediatric recurrent respiratory papillomatosis continue to be commonly used, including topical interferon alfa-2a, retinoic acid, and indole 3-carbinol/diindolylmethane (I3C/DIM). Topical cidofovir has shown efficacy in selected patients.

Currently, two HPV vaccines are available for the prevention, but not treatment, of HPV infection. One vaccine is protective against the two most common serotypes associated with cervical cancer (HPV serotypes 16 and 18) and the two most common serotypes associated with anogenital warts (HPV serotypes 6 and 11); this vaccine is licensed in the United States [32]. The second vaccine protects only against HPV serotypes 16 and 18 associated with cervical cancer; and is also licensed in the United States [33–35]. Although two approaches, preventive and therapeutic, have been pursued for HPV vaccines, to date only preventive vaccines that evoke a robust neutralizing antibody response to selected HPV serotypes have been successful. Further research to develop therapeutic vaccines that generate cytotoxic T lymphocytes and destroy HPV-infected neoplastic cells is under way [36].

## EPSTEIN-BARR VIRUS

Epstein-Barr virus (EBV) is a human herpesvirus that is most familiar as the cause of infectious mononucleosis. Most women of childbearing age have been infected asymptomatically in childhood. Because EBV cannot be isolated directly in tissue culture, serologic tests are used to detect recent primary or past infection.

Persons infected with EBV form IgG and IgM antibodies to viral capsid antigens (VCAs) soon after infection [37]. About 80% form antibodies to early antigens (EAs), which usually decrease to undetectable levels 6 months after infection. The presence of antibodies to EAs at later times after acute infection may indicate viral reactivation [38]. Antibodies to EBV-associated nuclear antigen (EBNA) develop 3 to 4 weeks after primary infection and probably persist for life, as do IgG antibodies to VCAs.

Prospective studies using antibodies to EAs as a marker of recent maternal EBV infection have yielded conflicting results. In a group of 719 women evaluated by Icart and Didier [39], pregnancies associated with early fetal death; birth of infants with a congenital abnormality, prematurity, or intrauterine growth restriction; and deaths or illnesses during the 1st week of life were more common in women who were positive for EA antibody during the first 3 months of pregnancy than in women who were not. Whether these women had a recent primary EBV infection or reactivation of an infection cannot be determined because EBV EA antibodies persist in some otherwise healthy adults and are associated with the reactivation of past EBV infection. In contrast, Fleisher and Bolognese [40] found that the frequency of antibodies to EA in pregnant women was 55% compared with 22% to 32% among nonpregnant adults, but the incidence of low birth weight, neonatal jaundice, or congenital anomalies was not increased among infants of women with anti-EA antibodies.

Primary EBV infection during pregnancy is unusual [41] because only 3% to 3.4% of pregnant women are susceptible [42,43]. Recent primary EBV infection is diagnosed by the presence of VCA IgG and IgM antibodies in the absence of antibodies to EBNA [44]. Six women were studied who had primary EBV infections during pregnancy as established by the presence of IgM antibody to VCA and the absence of antibody to EBNA in their sera [42]. Of these, only one woman had symptoms compatible with mononucleosis during pregnancy; she gave birth to a normal infant. Four of the remaining five pregnancies terminated abnormally. One woman had a spontaneous abortion, and the other three were delivered of premature

infants. All three of the premature infants were abnormal. One was stillborn, one had multiple congenital anomalies, and one was small for gestational age. The products of abortion and the premature infants were not studied for evidence of an EBV infection. The abnormal infants in this study did not have a characteristic syndrome, but instead had a variety of abnormalities.

Fleisher and Bolognese [45] identified three infants born to women who had had silent EBV seroconversion during the first trimester. Two infants were normal; one infant had tricuspid atresia. EBV IgM was not detected in cord blood serum, and EBV was not recovered from the cord blood lymphocytes. Three infants of mothers with a primary EBV infection and infectious mononucleosis were normal at birth and had no serologic or virologic evidence of intrauterine infection [46].

Early reports implicated EBV as a cause of congenital anomalies, particularly congenital heart disease; however, Tallqvist and colleagues [47] were unable to detect an increase in incidence of antibodies to EBV in children 6 to 23 months old with congenital heart disease compared with normal, age-matched controls. EBV may cause congenital heart disease in an individual case, but this study suggests that it is an uncommon cause of cardiac defects. Brown and Stenchever [48] described an infant with multiple congenital anomalies who was born to a mother who had a positive monospot test result 4 weeks before conception and at 16 and 36 weeks of gestation. In addition to the anomalies, which involved many organs, the infant was small for gestational age. Normal chromosomal complements were found on standard and G-banded karyotypes. The total IgM level in the cord blood was not elevated. Studies were not performed for IgM VCA antibody or antibody to EA, and no attempts were made to isolate EBV. Although the evidence that the mother had mononucleosis near the time of conception is convincing, there is no virologic evidence that EBV was the cause of the anomalies.

Goldberg and associates [49] described an infant born with hypotonia, micrognathia, bilateral cataracts, metaphyseal lucencies, and thrombocytopenia. Immunologic evidence suggesting possible EBV infection included an elevated total IgM level, the presence of IgM anti-VCA antibody at 22 days of age, and a delay in development of anti-EBNA antibody until 42 days of age. Weaver and coworkers [50] described an infant with extrahepatic bile duct atresia and evidence of intrauterine EBV infection; EBV IgM was identified in serum obtained when the infant was 3 and 6 weeks old, and persistent EBV IgG was seen at 1 year.

Although EBV cannot be recovered by standard tissue culture methods, the virus can be detected by its capacity to transform B lymphocytes into persistent lymphoblastoid cell lines. In studies conducted to identify cases of intrauterine EBV infection, Visintine and colleagues [51] and Chang and Blankenship [52] observed spontaneous transformation of lymphocytes obtained from cord blood, but it was not associated with EBV. EBV-transformed cells were not found in any samples of cord blood from 2000 newborns studied by Chang and Seto [53] or from 25 newborns tested by Joncas and associates [54,55]. One study used nested PCR methods for amplifying EBV DNA regions in circulating lymphocytes from 67 mother-infant pairs within 1 week of birth [56]. Approximately 50% of the women and two of the neonates were EBV PCR positive. Visintine and colleagues [51] studied 82 normal term infants, 28 infants with congenital anomalies, and 29 infants suspected to have congenital infections; they were unable to isolate EBV from any of these infants.

Two infants have been described in whom there was evidence of infection with EBV at birth [55,57]. A congenital cytomegalovirus (CMV) infection coexisted in both infants. Most of the clinical findings in the infants were compatible with usual findings in congenital CMV infections and included microcephaly, periventricular calcifications, hepatosplenomegaly, and inclusions characteristic of CMV in sections of tissues or cells in urinary sediments. One infant had deformities of the hands similar to those seen in arthrogryposis. Neither CMV nor EBV was isolated from the saliva or secretions of these infants. In the first infant, IgM antibody to EBV was present at birth, and EBNA-positive permanent lymphoblastoid cell lines were established on five occasions between 3 and 30 months of age. In the second infant, permanent lymphoblastoid cell lines were established from the peripheral blood at birth and from postmortem heart blood at 3 days of age. EBNA and EBV RNA were identified in these cells, and CMV DNA was identified in the cells from the liver of the same infant.

Attempts to isolate EBV from secretions obtained from the maternal cervix have been unsuccessful [51,53], but the virus can be detected at this site by DNA hybridization [58]. There is little evidence suggesting that natal transmission of EBV occurs. EBV was recovered, however, from genital ulcers in a young woman with infectious mononucleosis [59]. Fatal EBV infection was diagnosed by DNA hybridization of lymph node tissue from one infant who presented with failure to thrive, emesis, diarrhea, and a macular rash at 14 days of age, but this infection might have been acquired in utero [60].

EBV can be transmitted to newborns in the perinatal period by blood transfusion [51,54]. Permanent lymphoblastoid lines that contained EBV antigens were established by Joncas and coworkers [54] from the blood of two infants who had received transfusions. One of these infants did not develop permanent antibodies to EBV.

There is no evidence at present that EBV causes congenital anomalies. Because the early and the late serologic responses of young infants to a primary EBV infection differ from those found when a primary infection occurs at an older age [38,54,61], it would be difficult to screen large numbers of newborns for serologic evidence of an EBV infection sustained in utero.

## HUMAN HERPESVIRUS 6

Human herpesvirus 6 (HHV-6) is a member of the herpesvirus family that has been identified as a cause of exanthema subitum (i.e., roseola) [62–64]. The virus exhibits tropism for T lymphocytes and is most closely related to human CMV by genetic analysis [65].

Seroepidemiologic studies have shown that HHV-6 is ubiquitous in the human population, regardless of geographic area, and that it infects more than 90% of infants

during the first year of life [66–68]. IgG antibodies to HHV-6 are detected in almost all infants at birth, with a subsequent decline in seropositivity rates by 4 to 6 months of age as transplacentally acquired antibody is lost. The highest rate of acquisition of HHV-6 infection seems to occur during the first 6 months to 1 year of life as maternal antibodies wane. The seroepidemiologic evidence and restriction enzyme analysis of paired virus isolates from mothers and their infants suggest that the usual route of transmission is perinatal or postnatal [69].

No cases of symptomatic intrauterine HHV-6 infection have been confirmed since the agent was identified in 1986, although congenital infection has been documented and is estimated to occur at a frequency of 1% [70]. A case of intrauterine infection was documented by PCR in a fetus whose mother had human immunodeficiency virus (HIV) infection and HHV-6 in peripheral blood mononuclear cells [71], and 1 (0.28%) of 799 cord blood serum samples had IgM antibodies to HHV-6 [72]. Another study, using HHV-6 DNA PCR applied to cord blood specimens from 305 infants, showed a 1.6% (5 of 305) PCR positivity rate, suggesting in utero transmission [68]. Evidence of reinfection after presumed congenital HHV-6 infection also has been shown [73]. Primary HHV-6 infection, with its anticipated higher risk of transmission to the fetus, should be rare during pregnancy, however, because almost all women have been infected in childhood. Analogous to human CMV infection, the reactivation of maternal HHV-6, although it may be common during pregnancy, is not expected to cause symptomatic intrauterine infection.

In addition to the roseola syndrome, HHV-6 has been detected by PCR in peripheral blood lymphocytes obtained from infants younger than 3 months who had acute, nonspecific, febrile illnesses [74,75]. Two neonates who had fulminant hepatitis associated with HHV-6 infection have been described [76,77]. Other associations found among infants include a mononucleosis-like syndrome [78], pneumonitis [79], and one case report of possible immunodeficiency and pneumonitis associated with HHV-6 infection [80]. All clinical associations between disease in infants and HHV-6 infection must be evaluated with care, however, because of the evidence that most infants become infected with this virus within a few months after birth and that the virus persists after primary infection, as is characteristic of herpesviruses [71]. Clinicians also must be aware of the potential for false-positive results in serologic assays and in attempts to detect the virus by PCR [64].

## HUMAN HERPESVIRUS 7

Human herpesvirus 7 (HHV-7) was discovered in the peripheral blood lymphocytes of a healthy adult in 1990 [81]. HHV-7 belongs to the *Roseolovirus* genus within the Betaherpesvirinae subfamily, along with HHV-6 and CMV. Similar to HHV-6, it causes primary infection in most individuals during childhood. Clinically symptomatic infection with HHV-7 seems to be significantly less common and occurs later than with HHV-6.

Based on seroepidemiologic studies [82–84], HHV-7 infection is ubiquitous in childhood and generally occurs at a later age than HHV-6 infection. The average age at infection is about 2 years, and 75% of children are seropositive by 5 years of age. The primary mechanism of transmission is from contact with saliva of infected individuals. Because HHV-7 DNA has been detected in breast milk, breast-feeding may be another source of infection [85]. Antibodies to HHV-7 in breast milk may protect against infection, however, and in one study, breast-feeding was associated with a lower risk of early acquisition of HHV-7 infection [85,86]. HHV-7 DNA has been detected in 2.7% of cervical swabs obtained from women in their third trimester of pregnancy, but from none of the swabs of control women, suggesting that pregnancy may be associated with reactivation of HHV-7 [87]. Perinatal transmission from contact with infected maternal secretions is unknown, and neonatal infections with HHV-7 have not been reported [88]. Clinical symptoms are rarely associated with HHV-7 infection, but include nonspecific fever, with or without rash, which resembles exanthema subitum. Clinically apparent HHV-7 infections seem to have a high rate of central nervous system (CNS) involvement [89–92].

## INFLUENZA A AND B

Early investigations of the teratogenic potential of influenza virus were epidemiologic studies in which the diagnosis of influenza was not confirmed serologically [93]. In 1959, Coffey and Jessup [93] reported an incidence of 3.6% of congenital defects in 664 Irish women who had histories of having had influenza during pregnancy compared with 1.5% of 663 women who did not have symptoms compatible with influenza. CNS anomalies were the most common type of defect, and of these, anencephaly was the most frequent. These investigators presented some evidence that women who had a history of having had influenza in the first trimester were more likely to give birth to infants who had congenital anomalies than women who had influenza later in the pregnancy. This evidence provided credence to the report.

In a similar study conducted in Scotland, Doll and Hill [94] were unable to confirm that congenital anomalies occurred with a higher frequency in infants of women who had histories of influenza during pregnancy than in infants of women who did not. After reviewing the reported incidence of stillbirth related to anencephaly recorded by the Registrar General for Scotland, they concluded that there was a small increase in risk of anencephaly if the mother had had influenza during the first 2 months of pregnancy. In performing this analysis, certain assumptions were made because of the lack of precise data. Record [95] and Leck [96] analyzed the same data and were unable to find an association between influenza and malformations of the CNS. An increase in congenital defects in infants of mothers who had influenza-like symptoms at 5 to 11 weeks of gestation was reported by Hakosalo and Saxen [97]. Most of these anomalies involved the CNS, but there was no increase in incidence of anencephaly in infants of women who had symptoms compatible with influenza compared with women who remained asymptomatic.

All of these studies were undertaken during influenza epidemics. It was assumed that, under these circumstances, there would be a high correlation between a history of

influenza as elicited from the patient and infection with influenza virus. During the 1957 outbreak, Wilson and Stein [98] showed that 60% of pregnant women who denied symptoms of influenza had serologic evidence of having been recently infected. Conversely, 35% of women who stated that they had had influenza lacked serologic evidence of having been infected. Likewise, Hardy and coworkers [99] found that 24% of women who stated that they had had influenza lacked serologic evidence of past infection with the epidemic strain, and 39% of women with titers suggesting recent infection denied symptoms of influenza. MacKenzie and Houghton [100] summarized the reports implicating influenza virus as a cause of maternal morbidity and congenital anomalies and concluded that probably no association exists between maternal influenza infection and subsequent congenital malformations or neoplasms in childhood.

Several studies have been performed in which infection by influenza virus has been serologically confirmed. Hardy and coworkers [99] reported that the incidence of stillbirths was higher in 332 symptomatic pregnant women with serologically confirmed influenza infections than in 206 women with serologically confirmed infections who had remained asymptomatic or in 73 uninfected women. The control group of uninfected women was smaller than expected because the attack rate during the period of the study was very high. Major congenital anomalies occurred in 5.3% of women whose infections occurred during the first trimester compared with 2.1% of 183 women infected during the second trimester and 1.1% of 275 women infected during the third trimester. Supernumerary digits, syndactyly, and skin anomalies were excluded from these figures. Among infants of mothers infected during the first trimester, cardiac anomalies were the most common type of abnormality; none of these infants had anencephaly.

Griffiths and associates [101] observed a slight increase in congenital anomalies in infants born to women who had had serologically confirmed influenza during pregnancy compared with infants of women who had not; however, all of the infants with congenital anomalies were born to women who had had influenza in the second or third trimester, making it less likely that these anomalies were related to influenza. Monif and colleagues [102] did not document infection in any of eight infants born to mothers who had influenza A/Hong Kong infections in the second and third trimesters. Wilson and Stein [98] found no increase in congenital anomalies in women with serologic evidence of having been recently infected with influenza virus who had conceived during the 3-month period when influenza was epidemic.

Population-based epidemiologic studies have not shown that influenza infections during pregnancy are significantly associated with adverse perinatal outcomes. Influenza infections during pregnancy are more likely, however, to result in hospitalization for respiratory symptoms in pregnant women than in nonpregnant adults [103,104]. Hartert and associates [103] conducted a matched cohort study of pregnant women to determine pregnancy outcomes associated with respiratory hospitalizations during influenza seasons from 1985–1993. During those influenza seasons, 293 pregnant women were hospitalized for respiratory symptoms, at a rate of 5.1 per 1000 pregnant women. The prevalence of prematurity and low birth weight was not higher than a matched cohort of pregnant women hospitalized with nonrespiratory diagnoses. Pregnant women with asthma had higher rates of respiratory hospitalizations than those without asthma, and all of three fetal deaths in this cohort were singleton, late third trimester intrauterine fetal deaths in mothers who had asthma and were current smokers [103].

Intrauterine exposure to influenza virus does not cause a consistent syndrome. If there is a cause-and-effect association between influenza virus infections during pregnancy and congenital anomalies, the latter occur with low frequency. Hakosalo and Saxen [97] documented an increase in the use of nonprescription drugs during influenza outbreaks and suggested that drugs rather than infection with influenza virus may exert an erratic teratogenic influence. Many studies have investigated the possible association between influenza infection in pregnant women and subsequent development of bipolar affective disorders or schizophrenia among their offspring, with mixed results [105–107].

Viremia is rare during influenza infections, but it does occur. Few attempts have been made to show transplacental passage of the virus to the fetus. Ruben and colleagues [108] tested the cord sera of infants born to 22 mothers who had been pregnant during an influenza A/England/42/72 outbreak and who had had influenza hemagglutination inhibition titers to this virus of 1:16 or greater while pregnant. The investigators randomly collected 42 cord serum samples from infants who had been born on the same day as the selected infants. Of the 64 cord serum samples tested, a decrease in titer of fourfold or more was seen in four samples after treatment with 2-mercaptoethanol; this suggests that IgM antibody to influenza might have been present. Three of 16 cord blood samples tested gave positive lymphocyte transformation responses to influenza virus. All seven of the infants with evidence of antigenic recognition of influenza virus at birth had uncomplicated deliveries and remained healthy. Influenza A/Bangkok was isolated from the amniotic fluid of a mother with amnionitis and acute influenza infection at 36 weeks of gestation; the infant, who was born at 39 weeks, had serologic evidence of infection, but was asymptomatic [109].

Yawn and associates [110] studied a woman who developed influenza in the third trimester and died of pulmonary edema. A virus similar to the prototype strain $A_2$/Hong Kong/8/68 was isolated from the lung, hilar nodes, heart, spleen, liver, kidney, brain, and spinal cord of the mother and from the amniotic fluid and myocardium of the fetus. Ramphal and colleagues [111] studied another woman who died of complications of an influenza infection at term. A virus similar to strain A/Texas/77 was isolated from maternal tissues, but influenza virus was not isolated from any of the fetal tissues tested.

In contrast to intrauterine infections with influenza virus, which are rare, infections acquired by infants in the neonatal period are common. Passively transferred antibody to influenza virus may prevent symptomatic infections during the first few months of life if it is present in sufficient quantity [112,113]. Two cases of influenza A/Hong Kong/68 infection in infants who were younger than 1 month were described by Bauer and associates

[114]. The first infant developed high fever, irritability, and nasal discharge when 10 days old; the second infant, who was premature, developed fever and nasal congestion when 14 days old. Symptoms were restricted to the upper respiratory system, and both infants recovered within 4 days of onset of the illness. Influenza virus infection may be fatal in the neonatal period, however [115]. Several outbreaks of influenza virus infection have occurred in neonatal intensive care units. In general, illness has been mild [114,116]. Most of the eight infected neonates described by Meibalane and coworkers [116] had nonspecific symptoms, including apnea, lethargy, and poor feeding. Only two had cough or nasal congestion. None had tachypnea or respiratory distress, but three of five for whom chest radiographs were obtained had interstitial pneumonia.

Infants younger than 6 months cannot be protected by influenza vaccine. All health care professionals who care for high-risk newborns should receive the influenza A/influenza B vaccine annually in the fall. Pregnancy is not a contraindication for the administration of influenza vaccine [117,118].

During the 2009 H1N1 pandemic, pregnant women were found to be at high risk for severe influenza symptoms secondary to H1N1 infection, with up to 7.2 times higher risk of being hospitalized and 4.3 times more likely to be admitted to an ICU compared to non-pregnant women (MMWR 2010; 59:321-326). In a case series from New York City, in 2009, 16 pregnant and 1 postpartum women were admitted to an ICU or died. Nine of the women gave birth during their hospitalization; 8 of the infants were live-born, but one of those died shortly after birth, one infant was still-born, and 6 of the 8 live-born infants were admitted to a neonatal ICU. In California, all reported cases of pregnant women who were hospitalized or died due to H1N1 infection in 2009 were reviewed. Ninety-four pregnant and 8 postpartum women were identified, 95% were in their second or third trimester at the time of illness, one third had other underlying influenza complications besides pregnancy, 22 required intensive care and 8 died. The H1N1 maternal mortality ratio was 4.3 (NEJM 2010; 362:27-25). All 13 infants delivered during hospitalization survived and none had influenza.

## RESPIRATORY SYNCYTIAL VIRUS

Although respiratory syncytial virus (RSV) is a common cause of upper respiratory tract infection in children and adults, there is no evidence that the virus causes intrauterine infection. Maternal infection has no known adverse effect on the fetus. RSV infections are frequently acquired by infants during the first few weeks of life and are associated with a high mortality rate. Two thirds of all infants become infected with RSV in the 1st year of life, and one third of them develop lower respiratory tract symptoms, 2.5% are hospitalized, and 1 in 1000 infants die as a result of RSV infection [119].

It was originally thought that passively transferred maternal antibody to RSV contributed to the severity of the infection in young infants by causing an immunopathologic reaction in the lung [120]. Later studies of the age-corrected incidence of symptomatic RSV infections showed a relative sparing of infants who were younger than 3 weeks [121,122]. This is the period during which maternal antibody is the highest. In subsequent studies, no evidence was found that the presence of maternal antibody adversely influenced the course of infection in the infant [123]. Lamprecht and colleagues [124] found an inverse relationship between the level of maternal neutralizing antibody and the severity of the RSV infection in the infant. Glezen and coworkers [125] found that the quantity of neutralizing antibody to RSV in cord sera was lower in infants with proven RSV infections than in randomly selected infants. None of the infected infants who had antibody titers of 1:16 or greater developed serious infections. Some authors have suggested that breast-feeding decreases the possibility that an infant will have a serious RSV infection early in life [126]; however, this has not been a consistent finding in every study. Because breast-feeding and crowded living conditions affect the incidence of RSV infection in infants, it has been difficult to define effects attributable solely to breast-feeding. Infection with RSV in infants who are younger than 4 weeks may be asymptomatic; consist of an afebrile upper respiratory syndrome; or be accompanied by fever, bronchiolitis or pneumonia, and apnea [127].

RSV accounted for 55% of cases of viral pneumonia in infants younger than 1 month in one study that evaluated hospitalized infants over a 5-year period [128]. Most infants who died had underlying medical conditions that involved the heart or lungs [129,130]. Premature infants who have recovered from hyaline membrane disease and who have bronchopulmonary dysplasia are especially likely to develop severe infections. The A subtype of RSV may have the potential to cause more severe disease than the B subtype [131].

Nosocomial outbreaks that have occurred in nurseries caring for premature and ill term infants have varied in severity. Neligan and colleagues [132] described an outbreak in which eight infants were infected. The first symptom in all infants was the development of a clear nasal discharge when 10 to 52 days old. Cough developed 2 to 7 days later. Three infants developed wheezing, and only one infant was seriously ill. In the outbreak described by Berkovich and Taranko [133], 14 infants in a premature nursery became ill when 11 to 184 days old. Of the 14 infants, 93% had coryza, 86% had dyspnea, 64% had pneumonia, and 36% had fever. Upper respiratory tract symptoms began 1 to 8 days before the first dyspnea in 11 infants. Changes compatible with pneumonia were visible on chest radiographs 3 to 5 days before clinical evidence of lower respiratory tract involvement developed. The degree of illness in the nine infants studied by Mintz and associates [134] was mild in four, moderate in two, and severe in two. One infant was asymptomatic. The infants who were the most seriously ill had fever, cyanosis, pulmonary infiltrates, and respiratory deterioration. Infants with RSV infections have developed respiratory arrest as a result of apnea [135,136].

Most infants infected during nosocomial outbreaks of RSV in nurseries were born prematurely, but had attained 4 weeks or more in chronologic age at the time they developed the infections [134,135]. Two nursery outbreaks were associated with dual infections caused by

RSV and rhinovirus or parainfluenza virus 3 [137,138]. A diffuse viral pneumonia, which is indistinguishable from severe RSV pneumonia, can be caused in rare instances by parainfluenza viruses alone or, rarely, by adenovirus [139]. Hall and coworkers [140] showed that infants who are younger than 3 weeks when they become infected with RSV have a greater incidence of nonspecific signs and a lesser incidence of lower respiratory tract infection than infants who are older than 3 weeks at the time of infection. RSV has been recovered from the oropharynx of infants who were younger than 48 hours [141]. It may be difficult to recognize the index case when RSV is introduced into the nursery [142].

Infants who are younger than 1 month have a higher mean maximal titer of virus in their secretions than older infants [143]. Of the infected infants studied by Hall and coworkers [143], 96% shed virus for 9 days. Objects contaminated with secretions from infected infants may be important sources of infection in nursery personnel. RSV in infected secretions is viable for 6 hours on countertops, for 45 minutes on cloth gowns and paper tissues, and for 20 minutes on skin [144]. Evidence suggests that personnel are at least as important in spreading the infection to infants as are other infected infants housed in the same area and that infection control measures can reduce the risk of transmission [145–147].

Any infant with rhinorrhea, nasal congestion, or unexplained apnea should be segregated and investigated for RSV infection. Personnel should be made aware that this agent, which causes only mild colds in adults, can cause fatal illnesses in infants. The specific diagnosis of RSV infection should be sought for infection control purposes and because ribavirin treatment has some effectiveness in infants with lower respiratory infection caused by this virus [148–151]. Methods have been described for administering aerosol ribavirin safely to infants receiving mechanical ventilation [152,153]. Questions concerning the benefits of ribavirin therapy for RSV pneumonia and the indications for its use remain [146,154]. Despite numerous studies in the United States and Canada regarding the use of aerosolized ribavirin, no clear improvement in clinical outcomes is consistent across all studies of ventilated and nonventilated infants with RSV infection [155,156]. Ribavirin aerosol therapy is not routinely recommended for RSV infection [157].

Although the benefit of treatment with ribavirin is controversial, there is clear evidence for the benefit of prophylaxis against RSV infection in infants at high risk for complications. Several studies showed the benefits of RSV intravenous immunoglobulin among selected infants at high risk for moderate to severe complications owing to RSV infection [158]. Such high-risk patients include infants and children younger than 2 years with chronic lung disease who have required medical therapy for lung disease within 6 months of the RSV season and premature infants who were 32 to 35 weeks' gestation at birth. RSV intravenous immunoglobulin is contraindicated for infants with cyanotic congenital heart disease because of possible safety concerns. Subsequently, a humanized anti-RSV monoclonal antibody preparation, palivizumab, was developed for intramuscular administration and shown to reduce by 55% hospitalizations resulting from RSV infection in these high-risk infants [158]. Initial concerns regarding the safety of palivizumab among infants with cyanotic congenital heart disease have been allayed based on clinical trials. Because of its greater uniformity and ease of administration and its efficacy in infants with cyanotic congenital heart disease, palivizumab is now the preferred method of RSV prophylaxis [159].

Improved survival of infants with RSV infection and underlying cardiopulmonary disease has been reported with advances in intensive care management [160,161]. Nevertheless, families of infants with medical conditions that predispose to severe RSV disease should be advised to avoid the higher risk of exposure associated with group daycare [162].

## LYMPHOCYTIC CHORIOMENINGITIS VIRUS

Lymphocytic choriomeningitis virus (LCV) is spread from animals, primarily rodents, to humans. Person-to-person spread has not been described (Table 30–2) [163]. Mice and hamsters have been implicated most often as the source of human infections. When mice acquire LCV transplacentally or as newborns, they remain asymptomatic, but they shed the virus in their urine for months [164,165]. This phenomenon of "tolerance" has been extensively studied in laboratory-bred strains of mice. Domestic household mice also have been implicated as a source of human cases of infection with LCV [166].

Several outbreaks in animal handlers and in families have been traced to pet Syrian (or golden) hamsters (*Mesocricetus auratus*) [167,168]. Adult and newborn hamsters remain asymptomatic after infection with LCV and shed the virus in feces and urine for months [164]. In outbreaks in which human cases have been associated with contact with infected hamsters, the location of the hamster's cage correlated with attack rate. When the hamster's cage was in a common living area, 52% of 42

**TABLE 30–2** Sources of Maternal or Neonatal Infection

| Infectious Agent | Other People with Same Infection | Animal |
|---|---|---|
| Human papillomavirus | Yes | No |
| Epstein-Barr virus | Yes | No |
| Human herpesvirus 6 | Yes | No |
| Influenza viruses | Yes | No |
| Respiratory syncytial virus | Yes | No |
| Lymphocytic choriomeningitis virus | No | House mice, pet Syrian hamsters, laboratory rats, rabbits |
| Molluscum contagiosum virus | Yes | No |
| Rabies | — | Yes |

family members in contact with the hamster became infected [167]. In contrast, no one became infected when the cage was located in a more remote area, such as a basement or landing. LCV can be shed also by asymptomatic guinea pigs and rats [164,165,168].

Beyond the neonatal period, the illness caused by LCV is accompanied by fever, headache, nausea, and myalgia lasting 5 to 15 days [163,167,169]. In the outbreak of LCV described by Biggar and colleagues [167], fever occurred in 90% and headache occurred in 85% of patients. Myalgia occurred in 80% and was described as severe. The neck, shoulders, back, and legs were most often involved. Pain on eye movement occurred in 59%, nausea occurred in 53%, and vomiting occurred in 35%. About one fourth of the patients had a sore throat or photophobia. The illness was biphasic in 24% and was accompanied by swollen glands in 16%. A mononucleosis-like illness occurred in 6% of the patients characterized by intermittent fever, adenopathy, pharyngitis, extreme fatigue, and rash. Of patients with serologic evidence of having had an infection, 12% remained asymptomatic. Arthritis, encephalitis, and meningitis occurred in a few cases.

The diagnosis of infection with LCV can be made by isolation of the virus or by serology. The indirect fluorescent antibody titer may be positive the 1st day of symptoms [163,169]. The complement fixation titer generally does not increase until 10 days or longer after illness onset [163,168]. The neutralization titer increases late, usually after the 4th week, but persists the longest [163,168]. A positive indirect fluorescent antibody titer, a decreasing indirect fluorescent antibody or complement fixation titer, or an increasing neutralization titer suggests recent infection with LCV.

LCV infections during pregnancy may be underdiagnosed as causes of congenital infections and are associated with abortion, intrauterine infection, and perinatal infection. Ackermann and associates [170] described a 23-year-old woman who developed a febrile illness beginning 4 weeks after she assumed the care of a Syrian hamster. She was 7 months pregnant at the time of the illness and sustained a spontaneous abortion 4 weeks after onset of the fever. LCV was isolated from curettage material. Complement fixation antibodies to LCV were present initially, and neutralizing antibodies appeared later—a pattern compatible with recent infection. Diebel and coworkers [163] studied a pregnant woman who acquired LCV from a hamster and developed meningitis. One month after the onset of illness, a spontaneous abortion occurred. Biggar and coworkers [167] described a woman who acquired LCV during the first trimester of pregnancy. She had a spontaneous abortion 1 month after onset of the illness.

U.S. cases of 26 serologically confirmed congenital LCV infections identified from 1955–1996 were reviewed [171]; 85% (22 of 26) were in term infants with a median birth weight of 3520 g. The most common congenital abnormalities identified were chorioretinopathy (88%), macrocephaly (43%), and microcephaly (3%). There was a 35% (9 infants) mortality rate, with a 63% (10 of 16) rate of severe neurologic sequelae among reported survivors. One fourth of mothers had gestational exposure to rodents, and 50% of all women reported symptoms consistent with LCV infection.

Intrauterine infection of the fetus results in congenital hydrocephalus and chorioretinitis. In 1974, Ackermann and associates [172] reported that two children who were born to mothers who had been in contact with hamsters during the second half of pregnancy had hydrocephalus and chorioretinitis. Other problems included severe hyperbilirubinemia and myopia. The serologic pattern typical of recent infection was found in the mothers and infants and included a decreasing complement fixation titer and an increasing neutralization titer to LCV. Sheinbergas [169] found a statistically significant relationship between the presence of antibody to LCV and the occurrence of hydrocephalus in infants younger than 1 year. Thirty percent of 40 infants with hydrocephalus had indirect fluorescent antibody to LCV, whereas only 2.7% of 110 infants with other nervous system diseases had antibody to LCV. Fourteen (87.5%) of 16 infants who had serologically confirmed prenatal infection with LCV had hydrocephalus. Of these, six (37.5%) had been born with hydrocephalus, and the remaining eight developed it when 1 to 9 weeks old. Chorioretinal degeneration was found in 81%, and optic disk subatrophy was found in 56%. Mets and colleagues [173] performed ophthalmologic surveys among residents of a home for the severely mentally retarded, and sera from the 4 residents with chorioretinal scars and 14 residents with chorioretinitis were tested for *Toxoplasma gondii*, rubella virus, CMV, herpes simplex virus, and LCV. Two of the 4 residents with chorioretinal scars and 3 of the 14 residents with chorioretinitis had elevated antibody titers only to LCV [173].

Komrower and colleagues [166] described a mother who acquired LCV about 1 week before delivery. Despite segregation of the infant, LCV was acquired transplacentally or natally, and the infant subsequently became ill. The mother's initial symptoms included malaise, headache, fever, and cough. About 20 days after onset of symptoms and 12 days after delivery, increased numbers of cells and increased protein concentration occurred in the cerebrospinal fluid. The diagnosis of infection caused by LCV was confirmed by an increase in the mother's complement fixation titer from 1:2 to 1:64. The infant, who was probably premature, remained relatively stable until 11 days old, at which time seizures, stiff neck, and mild pleocytosis developed. The infant developed petechiae and died of a subarachnoid and intracerebral hemorrhage. LCV was isolated from the infant's cerebrospinal fluid and from mice caught in the home of the mother.

Because apparently healthy mice and hamsters may shed LCV chronically, pregnant women should avoid direct contact with these animals and with aerosolized excreta. Unless appropriate measures have been taken to ensure that laboratory animals are free of LCV, these precautions should apply to laboratory as well as domestic rodents. LCV causes spontaneous abortions. Hydrocephalus and chorioretinitis are common in infants who have survived intrauterine infection [169,172–174]. Women who acquire LCV infection during the weeks immediately before delivery may transmit the virus to their infants. Although the total number of intrauterine and perinatal infections from LCV is not large, the incidence of serious sequelae in the infant seems to be high. No treatment is available.

## MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a papular rash consisting of multiple discrete lesions that are acanthomas by histologic examination. The skin lesions are caused by a pox-like virus that has been difficult to study because it cannot be propagated in tissue culture. Epidemiologically, molluscum contagiosum is a disease of children and young adults. The virus may be transmitted by sexual conduct, given that the incidence increases among adolescents and young adults. Whether it is transmitted as a perinatal infection is unknown.

Wilkin [175] described five women who delivered infants at a time when they had the lesions of molluscum contagiosum in the genital area. None of the infants developed molluscum contagiosum. Mandel and Lewis [176] reported an infant who developed two papules on the thigh when 1 week old. These enlarged and were excised when the child was 1 year old. The results of histologic examination and the findings on electron microscopy were compatible with molluscum contagiosum. In 1926, Young [177] reported an infant with molluscum contagiosum of the scalp. The lesions appeared when the infant was 1.5 months old. No histologic studies were performed.

## RABIES VIRUS

Transplacental transmission of rabies virus to the human fetus has not yet been described, although transplacental transmission occurs in experimental infections in many species [178–183]. Spence and associates [184] described an infant who was born 2 days before the onset of the mother's first symptom of encephalitis. The mother died of rabies on the 4th postpartum day. Rabies virus antigens were shown in the cornea, lacrimal gland, and various parts of the brain by fluorescent antibody stain. The child survived despite the fact that the mother and infant lacked neutralizing antibodies to rabies at the time of the birth.

Two reports described the successful administration of horse antirabies hyperimmune serum and duck embryo vaccine to pregnant women [178,184]. Unusual untoward effects did not occur, and the infants were delivered at term and were healthy. The mothers did not develop serum sickness, anaphylaxis, or neurologic complications, but if they had, the viability of the fetus might have been threatened. Horse antiserum to rabies virus has been replaced by human rabies immunoglobulin. The chance of an adverse reaction to administration of human immunoglobulin is very small. The vaccine that was previously grown in duck embryos has been replaced with an inactivated vaccine derived from virus grown in human diploid fibroblast cells [185]. No serious reactions have been reported after administration of this vaccine, and it is possible to achieve titers that are about 10-fold higher than titers found after administration of the duck embryo vaccine.

Because of the high likelihood of fatal disease after the bite of a rabid animal, postexposure prophylaxis should always be given. Pregnancy is not a contraindication. When it is necessary to administer prophylaxis to a pregnant woman, human rabies immunoglobulin and human diploid cell vaccine should be used to minimize potential adverse effects on the pregnancy. After reviewing the available data, the Advisory Committee on Immunization Practices of the U.S. Centers for Disease Control and Prevention (CDC) has recommended human diploid cell vaccine to rabies virus as a preexposure immunization that is safe for use in pregnant women who will likely be exposed to wild rabies virus before completion of pregnancy [186].

## WEST NILE VIRUS

West Nile virus (WNV) is a mosquito-borne flavivirus that has caused epidemic infections in the United States since its introduction in 1999 [187]. Since then, three cases of intrauterine and breast-feeding transmission have been reported in the literature [188–190]. In 2002, a previously healthy woman at 27 weeks of gestation developed a febrile illness, followed by lower extremity paresis and meningoencephalitis. At 38 weeks of gestation, she delivered an infant with bilateral chorioretinitis and severe, bilateral white matter loss in the temporal and occipital lobes. Maternal, cord, and infant blood samples at birth were positive for WNV-specific IgM and neutralizing antibodies; cerebrospinal fluid from the infant was WNV IgM positive; and the placenta was WNV PCR positive [188]. A second reported case of intrauterine WNV infection occurring in the second trimester resulted in congenital chorioretinal scarring and severe CNS malformations of the newborn [189].

One case of probable breast-feeding transmission was reported in a woman who required red blood cell transfusions shortly after delivery. She began breast-feeding on the day of delivery and through the 2nd day of hospitalization. The woman had developed symptoms consistent with meningoencephalitis 6 days before delivery; subsequent evaluation of the units of transfused blood revealed 1 unit that was positive for WNV by PCR. Serum from the infant was positive for WNV-specific IgM at day 25 of life. The infant remained healthy at last report [190]. Although spontaneous abortions and stillbirths have been associated with flavivirus infections, these viruses have not previously been reported to be teratogenic. During 2002, the CDC investigated three other cases of maternal WNV infection in which the infants all were born at full term with no evidence of WNV infection or congenital sequelae; however, cranial imaging and ophthalmologic examinations were not performed on these infants [191].

No specific therapy is available for WNV infection, and the CDC does not recommend WNV screening of asymptomatic pregnant women. Pregnant women who have meningitis, encephalitis, acute flaccid paralysis, or unexplained fever in an area of ongoing WNV transmission should have serum and cerebrospinal fluid, if clinically indicated, tested for antibody to WNV. If WNV illness is diagnosed in the pregnant woman, ultrasound examination of the fetus should be considered no sooner than 2 to 4 weeks after maternal onset of illness, and fetal or amniotic testing can be considered. Infants born to women with known or suspected WNV infection during pregnancy should be evaluated for congenital WNV

infection. Prevention of WNV infection should include application of insect repellant to skin and clothes when exposed to mosquitoes and avoidance of peak mosquito-feeding times at dawn and dusk [191].

# CHAPTER 31 TOXOPLASMOSIS

Jack S. Remington • Rima McLeod • Christopher B. Wilson • George Desmonts*

CHAPTER OUTLINE

*Toxoplasma gondii* is a protozoal parasite that can cause devastating disease in the fetus and newborn yet remain unrecognized in women who acquire the infection during gestation. In addition, in most countries, congenital infection and congenital toxoplasmosis in the newborn go undiagnosed, thereby predisposing to the occurrence of untoward sequelae of the infection, including decreased vision or blindness, decreased hearing or deafness, and mental and psychomotor retardation. The cost for special care of children with congenital toxoplasmosis born each year in the United States alone has been estimated to be in the hundreds of millions of dollars.

*T. gondii* is ubiquitous in nature and is the cause of a variety of illnesses that previously were thought to be due to other agents or to be of unknown cause. Toxoplasmic encephalitis has proved to be a significant cause of morbidity and mortality in immunodeficient patients, including infants, children, and adults with acquired immunodeficiency syndrome (AIDS). Toxoplasmosis in domestic animals is of economic importance in countries such as England and New Zealand, where it causes abortion in sheep, and in Japan, where it has caused abortion in swine. In a majority of infected infants, clinical signs are not recognized at birth, but sequelae of the congenital infection are recognized or develop later in life. In this chapter, the term congenital toxoplasmosis refers to cases in which signs of disease related to congenital infection are present.

The history of *T. gondii* began in 1908, when Nicolle and Manceaux observed a parasite in the spleen and liver of a North African rodent, the gundi (Ctenodactylus gundi) and proposed the name *Toxoplasma* (from the Greek toxon, "arc") *gondii* [1]. The organism soon attracted attention as a cause of disease in animals, and in 1923, Janku, an ophthalmologist in Prague, described the first recognized case in humans [2]. He found parasitic cysts in the retina of an 11-month-old child with congenital hydrocephalus and microphthalmia with large macular scars. The parasite noted by Janku was later recognized to be *T. gondii* by Levaditi, who suggested a possible connection between congenital hydrocephalus and toxoplasmosis [3].

It was not until 1937, however, that recognition of toxoplasmosis as a disease of humans had a real impact on medicine. In that year, Wolf and Cowen in the United States reported a fatal case of infantile granulomatous encephalitis, and along with their collaborators performed numerous studies, which established *T. gondii* as a cause of prenatally transmitted human disease [4,5]. (Case 4 in the report by Paige and coworkers [6] is of special interest because it established beyond question that the infantile form of the infection was prenatal in origin.)

The discovery of *T. gondii* as a cause of disease acquired later in life has been credited to Pinkerton and Weinman. In 1940, they described a generalized fatal illness in a young man that was caused by this organism [7]. In 1941, Pinkerton and Henderson provided a clinical description of two fatal cases of an acute febrile exanthematous disease in adults [8], and in the same year, Sabin described cases of toxoplasmic encephalitis in children [9].

In 1948, Sabin and Feldman originated a serologic test, the dye test, that allowed numerous investigators to study epidemiologic and clinical aspects of toxoplasmosis to demonstrate that *T. gondii* is the cause of a highly prevalent and widespread (most often asymptomatic) infection in humans, and to define the spectrum of disease in humans [10]. It was not until 1969, some 60 years after the discovery of the parasite, that *T. gondii* was found to be a coccidian and that the definitive host was found to be the cat.

## THE ORGANISM

*T. gondii* is a coccidian and exists in three forms outside the cat intestine: an oocyst, in which sporozoites are formed [11,12]; a proliferative form, referred to as a tachyzoite; and a tissue cyst, which has an intracystic form termed a bradyzoite. (Because a single nomenclature has

*Deceased.

DOI: 10.1016/B978-1-4160-6400-8.00031-6

not been agreed on, the terms for each form are used as synonyms in this chapter.) For a more thorough discussion of the organism itself, including its cell biology, molecular biology, genetics, antigenic structure, and immunobiology, the reader is referred to reviews on these subjects [13–24].

## OOCYST

The enteroepithelial cycle occurs in the intestines of members of the cat family (see "Transmission" section) and results in oocyst formation (Figs. 31–1 and 31–2). Schizogony and gametogony appear to take place throughout the small intestine but especially in the tips of the villi in the ileum. In cats, the prepatent period from the ingestion of cysts to oocyst production varies, ranging from 3 to 10 days after ingestion of tissue cysts, from 19 to 48 days after ingestion of tachyzoites [25], and from 21 to 40 days after ingestion of oocysts [26].

Gametocytes appear throughout the small intestine from 3 to 15 days after infection. After zygote and oocyst formation, no further development occurs within the gut of the cat. Oocysts pass out of the gut with the feces; peak oocyst production occurs between days 5 and 8. Oocysts are shed in the feces for periods that range from 7 to 20 days. As many as 10 million oocysts may be shed in the feces in a single day. The fully sporulated oocyst is infective when ingested, giving rise to the extraintestinal forms. Within the cat, it also can give rise to the enteroepithelial cycle. Depending on the temperature and availability of oxygen, sporulation occurs in 1 to 21 days [27,28]. Sporulation takes place in 2 to 3 days at 24° C, 5 to 8 days at 15° C, and 14 to 21 days at 11° C [29]. Oocysts do not sporulate below 4° C or above 37° C [27].

## TACHYZOITE

Tachyzoites are crescentic or oval, with one end attenuated (pointed) and the other end rounded (see Fig. 31–1, *A* and *B*); they are 2 to 4 μm wide and 4 to 8 μm long. The organisms stain well with either Wright or Giemsa stain. This form of the organism is employed in serologic tests (e.g., Sabin-Feldman dye test, fluorescent antibody methods, agglutination test).

The tachyzoite form requires an intracellular habitat to survive and multiply. It cannot survive desiccation, freezing and thawing, or action of the digestive juices of the human stomach [30]. This form of the parasite is destroyed within a few minutes in gastric juice, but a relatively small proportion of parasites can survive in tryptic digestive fluid for at least 3 hours but not as long as 6 hours. The organism is propagated in the laboratory in the peritoneum of mice [31] and in tissue cultures of mammalian cells [32].

The tachyzoites occur within vacuoles [33] in their host cells (see Fig. 31–1, *B*), and a definite space and an intravacuolar network are present between the parasite and the vacuole wall [34]. Host cell mitochondria and endoplasmic reticulum are concentrated in the host cell at the edge of the vacuole [35]. Reproduction in the tissues is by endodyogeny [36]. This is a process of internal budding

in which two daughter cells are formed within the parent cell and are released with disruption of the parent cell. When additional nuclear divisions occur before the daughter organisms are completely separated, rosettes are formed; repeated endodyogeny results in a large collection of parasites within a cell.

The tachyzoite form is seen in the acute stage of the infection, during which it invades every kind of mammalian cell (see "Pathology," section). After host cell invasion, the organisms multiply within their vacuoles approximately every 4 to 6 hours and form rosettes. The cytoplasm becomes so filled with tachyzoites that ultimately the cell is disrupted, releasing organisms that then invade contiguous cells [37–39] or are phagocytosed [40]. Colonies of pseudocysts containing tachyzoites produced by endodyogeny may persist within host cells for prolonged periods without forming a true cyst. The duration of this type of infection *in vivo* is not known.

## CYST

The tissue cyst (see Fig. 31–1, *C* and *D*) is formed within the host cell and may vary in size, ranging from cysts that contain only a few organisms to large cysts, 200 μm in size, that contain approximately 3000 organisms [41]. This form of *T. gondii* stains well with periodic acid-Schiff (PAS) stain, which causes it to stand out from the background tissue. The cyst wall is argyrophilic and weakly positive for PAS staining. Such cysts are demonstrable as early as the first week of infection in animals [42] and probably persist containing their viable parasites throughout the life of the host [25]. Although they may exist in virtually every organ, the brain and skeletal and heart muscles (see Fig. 31–1, *C* and *D*) appear to be the most common sites of latent infection [43]. Cysts are spherical in the brain and conform to the shape of muscle fibers in heart and skeletal muscles (see Fig. 31–1, *D*). Because of this persistence in tissues, the demonstration of cysts in histologic sections does not necessarily mean that the infection was recently acquired.

The cyst wall is disrupted by peptic or tryptic digestion, and the liberated parasites remain viable for at least 2 hours in pepsin-hydrochloric acid and for as long as 6 hours in trypsin [30], thereby allowing them to survive the normal digestive period in the stomach and even longer in the duodenum. In the presence of tissue, the liberated organisms remain viable for 3 hours in peptic digestive fluid and for at least 6 hours in tryptic digestive fluid. Freezing and thawing, heating above 66° C, and desiccation destroy this tissue cyst form; however, the organisms can survive as long as 2 months at 4° C [30]. Tissue cysts are rendered nonviable when internal temperatures have reached 68°C or −208°C [44]. Until more data are available, it appears that freezing at −20° C for 18 to 24 hours, followed by thawing, should be considered adequate for cyst destruction [30,45,46].

Like the tachyzoite, the cyst develops within a host cell vacuole [47,48]. Cysts may attain a relatively enormous size while still within the host cell. Tissue cysts in the brain are preferentially located within neurons and are retained within viable host cells irrespective of size or age [49]. This would explain the long-term survival of latent infection because the intracellular location could provide the minimal metabolic requirements of the resting stage (bradyzoite) [49]. A number of factors lead to bradyzoite differentiation and cyst formation, including arginine starvation, alkaline or acidic pH, and interferon-γ (IFN-γ) stimulation of inducible nitric oxide synthase (iNOS) and nitric oxide [50–52]. Cysts can form in tissue culture systems devoid of antibody and complement [53–55]. Immunity is of prime importance in regard to the presence of the different forms of the parasite during the extraintestinal cycle in the infected host. During the acute, initial state of the infection, parasites are present mainly as tachyzoites, which are responsible for parasitemia and systemic infection. When the host has developed an immune response, the infection usually reaches a latent or chronic stage, during which cysts are present in many tissues, and in the immunocompetent host, parasitemia and systemic infection with tachyzoites have subsided. These schematic definitions of the stages of the infection are important to the later discussion on congenital transmission. These two stages were defined by Frenkel and Friedlander in 1952 [56] as the first and third stages of *T. gondii* infection. They also described a second, subacute stage as a hypothesis to explain the pathogenesis of lesions observed in congenital toxoplasmosis. The existence of an intermediate stage of uncertain duration also seems likely in cases with subclinical infection, during which both encysted parasites and low-grade systemic infection with tachyzoites are present in the immune host. Whether "dormant" tachyzoites are present during chronic infection in addition to tissue cysts is not known.

# Transmission

Congenital transmission of *T. gondii* from an infected mother to her fetus was the first form of transmission to be recognized [4]. Investigators in the reported cases raised two hypotheses in an attempt to explain congenital transmission. They considered that transmission might occur as a consequence of the acute, initial stage of the infection in a pregnant woman or as a consequence of a recrudescence (either local or systemic with recurrent parasitemia) of a chronic (latent) maternal infection during pregnancy.

Experimental studies of congenital infections in different animal species were helpful for understanding this form of transmission, but definitive data were not obtained until prospective studies were performed in humans in nations such as Austria, where screening for the diagnosis of *T. gondii* infection among pregnant women is routinely performed, and France, where screening is compulsory.

## *Congenital Transmission*

The excellent correlation between isolation of *T. gondii* from placental tissue and infection of the neonate, along with results obtained at autopsy of neonates with congenital toxoplasmosis suggesting that the infection is acquired by the fetus *in utero* through the bloodstream, has led to the concept that infection of the placenta is an obligatory step between maternal and fetal infection. A likely scenario is that organisms reach the placenta

during parasitemia in the mother. They then invade and multiply within cells of the placenta, and eventually some gain access to the fetal circulation.

## Maternal Parasitemia

**Acute Infection.** From pathology studies in patients with toxoplasmosis, and from experiments in animals, it can be concluded that parasitemia occurs during the acute, initial stage of both subclinical and symptomatic infections. In an attempt to define the magnitude and duration of the parasitemia during subclinical infection, inoculation of mice was performed with clots of blood taken from women with recent subclinical infections (Desmonts G, unpublished data); these were the first seropositive blood samples obtained from pregnant women who were previously seronegative and who had been tested repeatedly during pregnancy. Approximately 50 patients were examined, and none of the samples were found to be seropositive. Because this method has proved to be valuable for isolation of *T. gondii* from patients with congenital toxoplasmosis (Table 31–1) and from newborns with subclinical infections, the absence of demonstrable organisms in these women suggests that parasitemia during the acute stage of acquired subclinical infection is no longer present, at least by the method employed, once serum antibodies are detectable. Attempts at isolation of *T. gondii* from blood of more than 30 patients with toxoplasmic lymphadenopathy were unsuccessful (Remington JS, unpublished data).

If it is accepted that transmission of *T. gondii* from a mother to her fetus reflects that parasitemia occurred in the mother, evidence indicates that parasitemia occurs at an early stage of the mother's infection before the appearance of serum antibodies [57] and clinical signs (if signs occur). We have observed this in several cases of acquired toxoplasmosis in pregnant women in whom lymphadenopathy appeared during the first month after they had been delivered of newborns with congenital *T. gondii* infection. Precise data are not available on the timing of events that occur after initial infection in humans. The delay between initial infection and occurrence of parasitemia is not known. Important considerations include the duration of parasitemia during the initial stage of the infection and the actual time between the initial infection and the earliest appearance of demonstrable specific antibodies.

**TABLE 31–1** Parasitemia in Clinical Forms of Congenital Toxoplasmosis*

| Clinical Form | No. of Infants | No. with Parasitemia (%) |
|---|---|---|
| Generalized | 21 | 15 (71) |
| Neurologic or ocular | 29 | 5 (17) |
| Subclinical | 19 | 10 (52) |
| Total | 69 | 30 (43) |

**Infants were studied during the first 2 months of life, but no infants had detectable parasitemia after 4 weeks of age.*

*Adapted from Desmonts G, Couvreur J. Toxoplasmosis: epidemiologic and serologic aspects of perinatal infection.* In *Krugman S, Gershon AA (eds). Infections of the Fetus and the Newborn Infant. Progress in Clinical and Biological Research, vol 3, New York, Alan R Liss, 1975, with permission.*

**Chronic Infection (Persistent or Recurrent Parasitemia).** A systematic search for persistent parasitemia in humans, especially during pregnancy, has not been reported. Nevertheless, one case report bearing on this subject is pertinent here. Persistent parasitemia was evident in a clinically asymptomatic, otherwise healthy, 19-year-old primigravid woman during 14 months after she gave birth to a congenitally infected infant who died during delivery [58]. This parasitemia persisted despite treatment with pyrimethamine and sulfadiazine. During the period of parasitemia, the patient again became pregnant; the result of this second pregnancy was a healthy baby with no evidence of congenital toxoplasmosis. This case of persistent parasitemia is unique in our experience.

Huldt (Huldt G, personal communication to Remington JS, 1987) isolated *T. gondii* from the blood of an elderly but otherwise healthy woman 1 year after clinical lymphadenopathy. In another case, a woman 60 years of age with a suspected lymphoma had detectable parasitemia on several occasions during a period of 2 years. As has been observed in normal laboratory animals, parasitemia may be observed during chronic infection in the immunodeficient patient despite the presence of neutralizing antibodies in the serum [59].

## Demonstration of *Toxoplasma gondii* in Placentas

**Histologic Demonstration.** *T. gondii* organisms have been demonstrated histologically in human placentas [60–63]. (See also "Placenta" section under "Pathology.")

In 1967, Sarrut reported histologic findings in the placentas of eight patients with congenital toxoplasmosis, with microscopic demonstration of the organism in four of them [64]. She noted a correlation between the clinical pattern of neonatal disease and the presence of histologically demonstrable parasites. Both cysts and tachyzoites were numerous and easily demonstrated in three patients with severe systemic fetal disease, whereas parasites were microscopically demonstrable in only one of five patients (see also under "Pathology") with milder disease. Parasites were not noted in cases in which clinical signs of the infection were delayed until weeks after birth. On the contrary, results following injection of placental tissue into mice were positive in patients with congenital toxoplasmosis, and in those with subclinical infection [65].

## Isolation Studies

***Toxoplasma gondii* in Placentas During Acute Infection.** From the original studies performed in France in the 1960s, it was concluded that *T. gondii* frequently could be isolated from the placenta when acute infection occurred during pregnancy, but that such isolation was rarely if ever possible when infection occurred before conception [66]. This was true even for women with high antibody titers at the beginning of pregnancy, which suggested that infection might have been acquired shortly before conception. Similar results were obtained by Aspöck and colleagues [67]. These authors examined 2451 women who had decided on termination of their pregnancy. Of these women, 1139 (46%) were seropositive and 77 (3%) had a *T. gondii* indirect fluorescent

antibody test titer of 1:256 or higher. The researchers injected the products of conception of 51 of these 77 women into mice. None of the results were positive. Because the researchers had used the whole product of conception after induced abortion, this negative result suggests that this conclusion—that placental infection is seldom if ever present at the time of delivery in women with high antibody titers at the beginning of pregnancy—might also be true for decidua, embryos, and placental tissues obtained early in pregnancy from such women.

When infection is acquired during pregnancy, the frequency of isolation of *T. gondii* from placentas obtained at the time of delivery is dependent on when seroconversion occurred during pregnancy. Table 31–2 shows the results obtained in 321 such cases. The frequency of positive isolation depended on the trimester of pregnancy in which maternal infection was acquired: the later it was acquired, the more frequently were parasites isolated. The frequency of isolation also depended on whether the women received treatment. Organisms were isolated less often if spiramycin was administered before delivery. These data were collected in the 1960s and 1970s during surveys carried out by Desmonts and Couvreur [68], which were feasibility studies of measures for prevention of congenital toxoplasmosis. The measures became compulsory in France in 1978. For many years (in the laboratory of one of us [GD]), placental tissue of women considered to be at risk of giving birth to a child with congenital *T. gondii* infection was routinely injected into mice for attempts at isolation of the parasite. (The number of placental inoculations performed in the Laboratoire de Serologie Neonatale et de Recherche sur la Toxoplasmose, Institut de Puériculture de Paris, averaged 800 per year.) The results support the conclusions of the initial surveys: *T. gondii* organisms frequently were present in the placenta on delivery when the acute infection occurred during pregnancy; the later the infection was acquired, the more frequently the placenta was involved. When infection occurred during the last few weeks of pregnancy, placental infection was demonstrable in more than 80% of cases.

A virtually perfect correlation was observed between neonatal and placental infection (see "Diagnosis" section) when the mother did not receive treatment during gestation or duration of the treatment was too brief or an inadequate dose of spiramycin (less than 3 g) was used [69]. Among 85 pregnancies ending in delivery of a child with congenital *T. gondii* infection, isolation of *T. gondii* from placental tissue was successful in 76 of 85 cases (89%). If the fact that only a relatively small portion of the placenta was digested for the inoculation into mice is taken into account, the high proportion of positive results supports the concept that placental infection is an obligatory occurrence between maternal and fetal infection. It also demonstrates that if the mother receives no or inadequate treatment, placental infection persists until delivery. Nevertheless, placental infection may not be demonstrable by mouse inoculation on delivery of a child with congenital *Toxoplasma* infection when the mother received treatment during pregnancy. In the series of cases reported by Couvreur and colleagues [69], the proportion of placentas from which *T. gondii* was isolated was 89 of 118 (75%) if the mothers had received treatment for more than 15 days with 3 g per day of spiramycin. This proportion was 10 of 20 (50%) if pyrimethamine plus sulfonamides was added to treatment during the last months of pregnancy.

***Toxoplasma gondii* in Placentas During Chronic Infection.** A study was performed by Remington and colleagues (in collaboration with Beverly Koops) in Palo Alto, Calif., to determine whether *T. gondii* can be isolated from placentas of women with stable dye test titers. Of the 499 placentas obtained consecutively, 112 (22%) were from women with positive dye test results. The digestion procedure (see "Isolation Procedures" later under "Diagnosis") was performed on 101 of these placentas. *T. gondii* organisms were not isolated from any of them. Thus in the population studied, chronic (latent) infection with *T. gondii* does not appear to involve the placenta significantly. By contrast, *T. gondii* has been isolated with relative ease from the adult human brain [43], skeletal muscle [43], and uterus [70].

Another study in which an attempt was made to isolate the organism from placental tissue is that of Ruiz and associates in Costa Rica [71]. Much smaller amounts of tissue were injected into mice, but isolation was successful in 1 of 100 placentas. The dye test titer in the mother from whose placenta the organism was isolated was 1:1024. Adequate clinical and serologic data for the offspring were not provided. The researchers stated that

**TABLE 31–2** Attempts to Isolate *Toxoplasma** from Placenta at Delivery in Women Who Acquired *Toxoplasma* Infection During Pregnancy

*T. gondii* organisms were not demonstrable in the placental tissue by microscopic examination. This finding is not surprising in view of the findings of Sarrut [64]. The high dye test titer in this case might have been due to an infection acquired during pregnancy. Ruoss and Bourne failed to isolate *T. gondii* from 677 placentas of mothers who were delivered of viable infants and who had low *T. gondii* antibody titers [72]. It can be concluded from these studies that placental infection is extremely rare in pregnant women with chronic *T. gondii* infection.

## Fetal *Toxoplasma gondii* Infection and Congenital Toxoplasmosis

**Acute Infection in the Mother.** Direct data that demonstrate the frequency with which *T. gondii* is transmitted to the fetus during the period of acute infection in the mother come from prospective studies such as those performed by Desmonts and Couvreur [66], Kräubig [73], Kimball and colleagues [74], and Stray-Pedersen [75]. Fetal infection, the consequence of placental infection, depends on the time during gestation when maternal infection was acquired. Table 31–3 (which summarizes findings from the same group of cases as in Table 31–2, although the number of cases in both tables is not the same because placentas were available in only 321 of the 542 pregnancies) shows data collected in the 1960s and 1970s by Couvreur and Desmonts. In Table 31–4, children are classified into five groups: those with no congenital infection, subclinical congenital infection, mild congenital toxoplasmosis, severe congenital toxoplasmosis, and stillbirth or early death (shortly after birth). Children were considered to be free of congenital infection if they had no clinical manifestations suggesting congenital toxoplasmosis and if their results on *T. gondii* serologic testing became negative after disappearance of passively transmitted maternal antibodies. Congenital infection was classified as subclinical if no clinical signs of disease related to toxoplasmosis occurred during infancy. Clinical disease was considered to be mild if the infant was apparently normal, with normal development on follow-up evaluation. An example of mild disease is that of a child with no mental retardation or neurologic disorder on later examination but with isolated retinal scars discovered during a prospective eye examination (or, in one case, isolated intracranial calcifications on radiographic examination) performed because the child was at risk of having congenital *T. gondii* infection, having been born to a mother who acquired the infection during gestation. Cases were considered to be severe if both chorioretinitis and intracranial calcifications were present or if mental retardation or neurologic disorders were present. From the results shown in Table 31–3, the subclinical form was by far the most frequent presentation of congenital *T. gondii* infection; severe cases with survival of the fetus were infrequent.

In 500 pregnancies, it was possible to ascertain the trimester during which *T. gondii* infection had been acquired (See Table 31–4). *T. gondii* infection occurred in the fetus or was present in the newborn in 14%, 29%, and 59% of cases of maternal infection acquired during the first, second, and third trimesters, respectively. The proportion of cases of congenital toxoplasmosis was higher in the first- and second-trimester groups than in the third-trimester group. This was especially true for severe congenital toxoplasmosis (including cases with stillbirths, perinatal deaths, or severe neonatal disease). No case of severe toxoplasmosis was observed among the 76 offspring of mothers who had acquired *T. gondii* infection during their third trimester. Approach to detection and management of infection acquired during gestation determines and can modify severity of infection detected in

**Severe ocular or neurologic disease occurred only when infants were born to mothers from foreign countries where there was no screening during pregnancy (e.g., Morocco, Algeria, United Kingdom), they were not screened, or mothers were immunodeficient or erroneously considered immune. It also is noteworthy that in one hospital in France, in 1957, among 1085 premature infants, 7 had toxoplasmosis, whereas in this same hospital between 1980 and 1990, among approximately 10,000 premature infants, 2 had toxoplasmosis.*
CNS, *central nervous system.*

infants and their later outcomes [76–79]. Of interest, after systematic serologic screening and treatment for *T. gondii* infection acquired in gestation was introduced in France in 1978, the frequency of severe toxoplasmosis diagnosed in newborns diminished remarkably (Table 31–5). This is discussed in more detail under "Effects of Systematic Screening of Pregnant Women at Risk on the Prevalence of Congenital *Toxoplasma gondii* Infection and of Congenital Toxoplasmosis."

Experience acquired since 1978 [80–83] has confirmed these earlier findings: Transmission of the parasite to the fetus was dependent on the time of acquisition of maternal infection during pregnancy. The proportion of cases that resulted in congenital *T. gondii* infection was very low if maternal infection was acquired during the first few weeks after conception. The later the maternal infection was acquired, the more frequent was transmission to the fetus. The frequency of congenital infection was 80% or higher if maternal infection was acquired during the last few weeks before delivery and if it was not treated. Table 31–6 shows the frequency of transmission by gestational age observed in a group of 930 women with acute *Toxoplasma* infection acquired during pregnancy who were referred to the Institut de Puériculture in Paris for prenatal diagnosis. The incidence of transmission rose from 1.2% when maternal infection occurred around the time of conception to 75% when it occurred close to term. These data were updated by Hohlfeld and coworkers [77], whose report includes the 2632 pregnant women for whom a prenatal diagnosis was performed between 1983 and 1992 (Table 31–7). The observed incidence of transmission rose from 0% when maternal infection was acquired before week 2 of pregnancy to 67% when it was acquired between weeks 31 and 34. The incidence of transmission remained very low, less than 2%, when maternal infection was acquired during the first 10 weeks of gestation. It rose sharply when maternal infection was acquired during weeks 15 to 34.

To appropriately interpret the data provided by Hohlfeld and coworkers, a number of points deserve discussion. Their patients were referred to the Institut de Puériculture for prenatal diagnosis. Thus cases with fetal death in utero before the time of amniocentesis were not included. The consequence is that the incidence of congenital infection when maternal infection occurred during the first few weeks of pregnancy is slightly underestimated. For example, when Daffos and colleagues reported the first 746 cases from this same series, they [82] estimated the incidence of transmission to be 0.6% among 159 women with "periconceptional infection" and 3.7% among 487 women whose infection was acquired between weeks 6 and 16 of gestation. The observed incidence rates were 1.8% and 4.7%, respectively, if those fetuses that died in utero because of congenital toxoplasmosis before the time of blood sampling were included in the report. Another consequence of the

recruitment of the cases reported by Hohlfeld and coworkers is that the number of cases with acquired maternal infection after week 26 of gestation is small because maternal infection acquired late during pregnancy was not discovered early enough to allow for performance of a prenatal diagnosis. The incidence of congenital infection was reported to be 194 of 2632 (7.4%). If, however, one excludes 100 cases of maternal infection acquired before week 2, and 351 in which gestational age at the time of maternal infection was unknown, the distribution of cases would be as follows: maternal infection acquired at gestational age 3 to 14 weeks, 1398 cases; 15 to 26 weeks, 745 cases; and 27 to 34 weeks, 38 cases. Most of the cases studied by Hohlfeld and coworkers occurred in women who acquired infection early in pregnancy. If cases of maternal acquired infection had been equally distributed through each of the weeks of gestation, from weeks 3 to 34, the adjusted mean transmission rate would have been 19.5%. The transmission rate observed by Jenum and associates in Norway [84] was 11 of 47 (23%).

A higher transmission rate, 65 of 190 (34%), was observed in a series of 190 consecutive cases of maternal acute *Toxoplasma* infection, each of whose sera was examined in a single laboratory in Paris (Thulliez P, personal communication to Desmonts G, 1999). These cases were more equally distributed in regard to gestational age at time of infection. The incidence rates of congenital infection in this series of 190 women were as follows: 4 to 16 weeks, 5 of 44 (11%); 17 to 28 weeks, 15 of 71 (21%); and 29 to 40 weeks, 45 of 75 (60%). In another series, reported by Dunn and associates [83], the mean rate of transmission was 29% in 603 cases studied in Lyon between 1987 and 1995.

A critical point to remember in reviewing the data obtained in the European countries where screening for *Toxoplasma* infection during pregnancy is routinely performed is that most patients are treated during pregnancy, which probably reduces the incidence of transmission of the parasite. The frequency of congenital toxoplasmosis (i.e., of fetal lesions or of clinical manifestations in the infant with congenital infection) also is highly dependent on the time of acquisition of maternal infection during pregnancy. The earlier maternal infection was acquired, the higher was the prevalence of fetal or neonatal disease among infants with congenital *T. gondii* infection.

A number of observations suggest that *T. gondii* may be present in the placenta but is transmitted to the previously uninfected fetus only after a delay. This delay has been termed the prenatal incubation period by Thalhammer [85,86]. Placental infection is a potential source of infection of the infant even long after maternal parasitemia has subsided. This has been documented in studies in which, after induced abortions, samples of fetal tissues and placentas were injected into mice in an attempt to isolate *T. gondii*. Table 31–8 shows the results obtained in 177 such cases in which no attempt at prenatal diagnosis of fetal infection had been made. Isolation attempts were successful from placentas in 10 cases (6%). In 8 of the 10 cases, placental and fetal tissues were injected separately and *T. gondii* organisms were isolated solely from the placentas and not from the fetus in four of those eight cases. The fetuses were not infected at the time the pregnancies were terminated. In one of these cases, pregnancy was terminated at week 21 in a woman who had acquired her infection shortly before the fourth week of gestation. This case demonstrates that delay between maternal and fetal infection may be longer than 16 weeks. In other cases, the delay may be much shorter. Among 22 pregnancies terminated because congenital *T. gondii* infection had been demonstrated in the fetus by prenatal diagnosis (see "Prenatal Diagnosis of Fetal *Toxoplasma gondii* Infection" in "Diagnosis" section) (data not included in Table 31–8), the time that elapsed between maternal and fetal infection evidently was less than 8 weeks in 2 cases, less than 6 weeks in 2 cases, and less than 4 weeks in 1 case. The case histories also suggested that the later during gestation maternal infection occurred, the shorter was the delay between maternal and fetal *T. gondii* infection (Table 31–9). The data of Daffos demonstrate that it is almost always first- and second-trimester infections that are associated with substantial brain necrosis and hydrocephalus [82]. Recent data reveal that the magnitude of fetal involvement correlates with the amount of parasite DNA in amniotic fluid (see "Polymerase Chain Reaction Assay" ["Diagnosis"] and "Prevention") [87].

The severity of the disease depends on the age of the fetus at the time of transmission (see Table 31–9). This is determined both by the time during pregnancy when

maternal infection occurs and by the duration of the delay between maternal infection and transmission to the fetus (prenatal incubation period). The earlier the fetus is infected, the more severe the disease in the newborn. The likelihood that transmission will occur early in fetal life is greater when the mother acquires her infection during the first or second trimester of pregnancy.

Results of examination of fetuses after induced abortion agree with these conclusions. Among the 177 cases in which pregnancies were terminated without any prior attempt at prenatal diagnosis (see Table 31–8), results of inoculation tests of fetal tissues were positive in 4 cases. In each of these 4, macroscopic lesions were evident on gross examination of the aborted fetus at autopsy. The same was true for 22 fetuses of women in whom the decision to terminate the pregnancy was made after fetal infection was demonstrated by isolation of *T. gondii* from amniotic fluid or from cord blood samples obtained in an attempt at prenatal diagnosis [82]. Each of these 22 fetuses had multiple necrotic foci in the brain, even when appearance on a previous ultrasound examination (performed before the pregnancy was terminated) was normal.

Transmission during the third trimester almost always results in either subclinical infection or mild congenital toxoplasmosis. Exceptions have been noted: In two cases (Desmonts G, unpublished observations) in which maternal infection was acquired after 30 weeks of gestation, the offspring had severe systemic disease and died in the newborn period.

By collecting data from pregnancies that resulted in birth of severely damaged infants, it was possible to define more precisely the weeks of pregnancy during which infection produces the greatest risk of severe congenital toxoplasmosis in the newborn infant. The period of highest risk was weeks 10 to 24 [80]. Although the incidence of transmission to the fetus is highest during weeks 26 to 40, it results in milder infection in the newborn. Weeks 1 to 10 constituted a low-risk period because transmission to the fetus was infrequent. Although infrequent, cases have been observed in which infection was acquired before week 7, or even shortly before conception, which resulted in the birth of severely damaged infants. The attempt at prenatal diagnosis by Daffos and associates [82] in 159 cases of periconceptional maternal infection (i.e., infections that, as judged by serologic test results, had been acquired at the time of conception or within a few weeks after conception) revealed fetal infection in only 1.8% of cases (see earlier). Thus in these circumstances, transmission of parasites is infrequent.

A question that is frequently asked when toxoplasmic lymphadenopathy is diagnosed in women of childbearing age or when serologic test results in a sample of serum drawn for routine testing very early in pregnancy suggest recently acquired *T. gondii* infection is as follows: How long before pregnancy is acquisition of *T. gondii* infection to be considered a risk factor for transmission of the parasite to the fetus in a future pregnancy? The answer is that if toxoplasmic lymphadenopathy was already present at the time of conception, and/or if two samples of serum, the first drawn before the eighth week of gestation and the second 3 weeks later, are examined in parallel and have identical IgG titers, the initial stage of the infection probably occurred before conception. The avidity test also is helpful in this setting because high-avidity IgG antibodies develop at least 12 to 16 weeks (depending on the test kit used) after acquisition of infection. Thus the presence of high-avidity antibodies indicates that infection was acquired more than 12 to 16 weeks earlier (see also later discussions of serodiagnosis and avidity assays) [88–90]. In these conditions, the risk for congenital *T. gondii* infection is extremely low. Unfortunately, accumulated data do not allow for a more definitive answer. Cases that demonstrate that the exception does occur have been reported. Of special interest are cases in which the diagnosis of toxoplasmic lymphadenopathy was well established before pregnancy occurred because they provide reliable information in regard to the timing of events (clinical signs in the mother, beginning of pregnancy, and the development of signs, if any, in the infant). A summary of the history of the first reported case [80,91] appeared in the third and fourth editions of this book [92,93]. Another case was reported by Marty and coworkers in 1991 [94], and a third was reported by Vogel and associates in 1996 [95]. The time elapsed between the occurrence of lymphadenopathy and conception was 2 months for the first case and 3 and 2 months, respectively, for the next two cases. The patient described by Marty and coworkers received spiramycin for 6 weeks at the time of lymphadenopathy; however, she did not receive treatment during pregnancy. Neither the first (studied by Desmonts) [93] nor the third (Vogel) mother received any treatment. In the three cases, no specific sign of congenital toxoplasmosis was recognized in the newborn (except possibly in the case reported by Marty and coworkers, in which slight splenomegaly was noted in the neonate). Strabismus was noted at the age of 3 months in the first case. None of the infants was given treatment before the diagnosis of congenital toxoplasmosis infection was established. Definitive diagnosis was made in two infants when obstructive hydrocephalus developed at the ages of 4 months and 9 months, respectively. In the case described by Marty and coworkers, infection was still subclinical when the diagnosis was made at the age of 8 months because of an increase in the antibody load (see the "Diagnosis" section).

The clinical patterns and the delayed antibody response observed in the infants are highly suggestive that transmission of the parasite to the fetuses occurred after maternal IgG had reached a significant level in the fetal blood (i.e., after 17 to 20 weeks of gestation), and probably later in the patient (described by Marty and coworkers) whose infection remained subclinical, despite absence of treatment before the eighth month of life.

These three cases demonstrate that infection in the 3 months before conception does not always confer effective immunity against congenital transmission. Transmission rarely occurs in these conditions, however. In our experience [80], no other example of congenital infection has arisen among several hundred cases in which toxoplasmic lymphadenopathy occurred before pregnancy. The advice given (by G Desmonts) was that patients infected in the 6 months before conception should be treated with spiramycin. This intervention possibly reduced the incidence of congenital infection among the offspring of these patients.

That fetal infection is rare when maternal acquisition of *T. gondii* infection has occurred even a short time before pregnancy is in agreement with the observation first made by Feldman and Miller [96], and amply confirmed since, that congenital infection does not occur in siblings (except twins) of a child with congenital toxoplasmosis. Several exceptions have been reported. In one instance described by Garcia, congenital *T. gondii* infection affected offspring of two successive pregnancies [60]. The first infant, delivered by cesarean section for fetal distress at the seventh month of gestation, died at 24 hours with multiple organ involvement with *T. gondii*. About 5 months after delivery of this infant, the mother again became pregnant. This pregnancy ended in spontaneous abortion of a macerated fetus at about the sixth month of gestation. Microscopic examination revealed *T. gondii* infection in both cases, in fetal and placental tissue. Although the proof rests solely on histologic findings, the data presented in these cases appear incontrovertible. Silveira and colleagues [97] also reported that *T. gondii* had been transmitted from a Brazilian mother infected 20 years earlier. The mother had a chorioretinal macular scar and positive result on serologic tests for *T. gondii* infection over a 20-year period. She was without known immunocompromise and transmitted *T. gondii* to her fetus. Details of the evaluation for immunocompromise and clonal type of parasite were not available (Silveira, personal communication to J Remington, 2003). Manifestations in the infant included IgG and IgM specific for *T. gondii*, a macular scar, and a cerebral calcification.

Two cases of transmission to the fetuses of women with subclinical infection acquired before pregnancy also have been published in France. Time of infection was well established in both cases because sera drawn before conception were available for comparison with the mandatory sample taken at the beginning of pregnancy [98,99]. In both cases, sera were negative for *T. gondii* antibodies 7 months before pregnancy and found to be positive, with a high but stable titer of IgG antibodies at 3 and 4 weeks of gestation, respectively. Thus infection had occurred about 1 to 2 months before conception in both cases. In both, prenatal diagnostic testing proved positive, and severe fetal lesions were demonstrated after termination of the pregnancies. Therefore, it is well established that the acute subclinical infection in a pregnant woman can result in fetal infection and congenital toxoplasmosis, even when acquired by the mother before conception.

Serologic screening tests for acute *T. gondii* infection during pregnancy usually are performed at weeks 8 to 12 of gestation. If the results suggest a recently acquired infection, it formerly was difficult, even with the help of a second sampling of serum 3 weeks later, to decide whether infection occurred before or after the time of conception (see "Diagnosis" section). These cases were classified as "periconceptional," and in our practice (Desmonts G) [91,100], these women were managed as if they had been infected during gestation (spiramycin treatment and prenatal diagnosis). The transmission rate observed after "periconceptional" infection was 3 of 161 (1.8%) [82]. With the availability of the avidity assay, acquisition can be more readily dated regarding whether it occurred before conception if the test is performed during the first 12 to 16 weeks of gestation.

It is apparent that the rate of transmission of the parasite from a woman to her fetus after the acute infection rises from virtually zero, when *T. gondii* infection was acquired several months (the exact number is unclear) before pregnancy, to about 2% (or slightly less), when acquired at about the time of conception. An important point is that the transmission rate remains low for several weeks (approximately 10) after the beginning of pregnancy. After the tenth week of gestation, a shift occurs from this low transmission rate toward a steeply increasing incidence of congenital infection in relation to the gestational age. This shift was observed in the 11- to 14-week gestational age group in the series reported by Hohlfeld and coworkers [77] and after week 13 in the series reported by Dunn and associates [83]. Several hypotheses might explain this shift from a low toward a steeply rising risk of transmission. One relies on a truism: Congenital toxoplasmosis is a fetopathy, resulting from a placental infection. Thus a placenta and a fetus are necessary for the disease to develop. Hence, congenital *T. gondii* infection, when resulting from an infection acquired by the mother before the formation of the placenta, is the consequence of a recurrent parasitemia. The incidence of transmission in this situation depends on the frequency of recurrent parasitemia in a woman whose cell-mediated immunity with regard to *Toxoplasma* has not yet fully developed (see the "Pathogenesis" section). When maternal infection is acquired later during pregnancy, the parasite can reach the placenta during the initial parasitemia, which occurs in the mother before the development of any immune response. This mode of transmission is more effective for colonization of the placenta by the parasite. The later the infection occurs in the fetus, however, the less severe the disease because immunologic maturation has had time to develop.

A summary of the data just presented is shown in Figure 31–3, in which percentages of risk are given, to suggest a range in magnitude and not necessarily exact data. It also should be noted that the data used in this figure were obtained from women almost all of whom received spiramycin treatment during pregnancy. Hence, the outcome in the fetuses may have been more severe, both for transmission rates and for severity of infection, if results from untreated pregnancies had been used.

**Chronic Maternal *Toxoplasma* Infection.** Data obtained in prospective studies have established that chronic (or latent) maternal infection, per se, is not a risk for congenital infection [96]. Also, as a rule, evidence of previous chronic (latent) infection signifies that the future mother is not at risk of giving birth to a child with congenital *T. gondii* infection. These observations constitute the basis for the preventive measures that have been adopted by and have proved effective in countries such as Austria and France [100–102].

However, several reports suggest that chronically infected but immunocompromised mothers may rarely transmit the infection to their fetus [91,103–105]. Four of the cases were reported from France. This is not surprising because such cases usually are observed only in countries where screening for *Toxoplasma* infection during pregnancy is performed routinely.

| Weeks of gestation when maternal infection occurred | Transmission rate* (incidence of congenital infection | Prevalence* of congenital toxoplasmosis (mild, moderate, or severe) among fetuses or infants with congenital infection | Risk for the mother of giving birth to a child with severe congenital infection |
|---|---|---|---|
| 6 months (?) before pregnancy | Virtually 0 | ≥80% | Low risk (low transmission rate) |
| Conception | 2% | | |
| | | High prevalence ≥80% | |
| 10th week | 3% | | Highest risk |
| 24th week | Increasing to | ≥80% | |
| 30th week | | 20% | Low risk (congenital infection is frequent but mainly mild) |
| | | Low prevalance | |
| Delivery | ≥80% | 6% | |

*Percentages are given as a range according to what has been observed among women, most of whom were treated with spiramycin during pregnancy.

**FIGURE 31–3** Transmission rate and prevalence of congenital *Toxoplasma* infection or congenital toxoplasmosis among offspring of women with acute *Toxoplasma* infection in relation to gestational age at time of maternal infection.

A summary of the histories of the four cases follows: The women were known from previous pregnancies to have low and stable titers of IgG antibodies, which is characteristic of past infection and immunity. The same low titer of IgG was present at the beginning of the new pregnancy. Thus these women were considered to be immune, so that their fetus was judged not to be at risk. Treatment was therefore not given during gestation. Congenital *T. gondii* infection was demonstrated in each case: A subclinical infection was noted when the child was 12 months of age in one case (the history of which was published in previous editions of this book) [92,93]; spontaneous abortion occurred at 12 weeks of gestation, with demonstration of the parasite in fetal tissues in another case [103]; and congenital toxoplasmosis (chorioretinitis) was diagnosed at birth in the third case [104] and at 9 months of age in the fourth case [105]. In each of the four cases, a serologic relapse occurred during pregnancy, as evidenced by a significant increase in IgG antibodies that reached high titers in each woman. In three of the women, samples of sera drawn during pregnancy were available for retrospective examination. Of interest is that in these three cases, IgA antibodies were present at the beginning of the serologic relapse. An IgM response was noted in only one woman. Serologic relapse had occurred between weeks 8 and 11 of gestation in the case ending in abortion and after weeks 10, 16, and 19, respectively, in the other three cases. Silveira and colleagues [97] also reported that *T. gondii* had been transmitted from a Brazilian mother infected 20 years earlier, as described.

Even if some cases have gone unpublished (Dr. Jacques Couvreur has data on two additional cases, as described in a personal communication to Desmonts G, 1999), the examples of offspring with congenital *T. gondii* infection born to mothers who, at the beginning of pregnancy, had serologic test results that established the presence of a chronic (latent) infection are exceptional. When this does occur, immunologic dysfunction must be suspected as having been the cause. The first case we observed [92,93] was that of a woman who had a low $CD4^+/CD8^+$ ratio associated with Hodgkin disease, from which she had recovered 2 years before becoming pregnant. She also previously underwent a splenectomy. No immunologic dysfunction was demonstrated in the other three women. Reinfection

with oocysts of another *T. gondii* strain was suggested as an explanation for the cases observed by both Fortier and Gavinet and their coworkers [103,105]. Each woman had contact with kittens at the beginning of or during week 20 of gestation, respectively.

Transmission of *T. gondii* from mother to fetus has been observed in immunodeficient women owing to reactivation of the chronic infection, primarily in patients with AIDS (see "Congenital *Toxoplasma gondii* Infection and Acquired Immunodeficiency Syndrome" later, under "Clinical Manifestations"). It also has occurred as a consequence of other immunocompromised states that appear to have resulted in an active but subclinical infection in the chronically infected pregnant woman. One case was reported in the third and fourth editions of this book [92,93,106]. Two additional cases were published in 1990 [91], and a fourth in 1995 by d'Ercole and colleagues [107]. The immunologic dysfunction was associated with lupus erythematosus in three of the four patients and with pancytopenia in one. This last patient, and one of those with lupus, also previously had a splenectomy. Each of the four patients was given corticosteroids during gestation. Three [91] did not receive treatment for their *T. gondii* infection. The serologic evidence for (chronic) active infection was the unusually high IgG titers that had been present since childhood in two of the cases. One of these women gave birth to an infant with severe congenital toxoplasmosis that resulted in the death of the child at the age of 3 months. Congenital toxoplasmosis was diagnosed in the other case when chorioretinitis occurred in the infant at the age of 4 months. In one of the four mothers, the IgG titer rose from a relatively low titer at the beginning of pregnancy to 800 IU, and a weakly positive IgM test titer developed. One of her twin infants, a boy, died at the age of 9 days from toxoplasmic encephalomyelitis. His twin sister had subclinical congenital *T. gondii* infection.

The cases just described demonstrate conclusively that the presence of a chronic, yet active *T. gondii* infection in an immunocompromised pregnant woman results in a significant risk of congenital infection for the fetus and newborn. In addition to women with AIDS, this is especially true for women who must receive long-term treatment with corticosteroids during gestation [108]. Treatment of HIV infection in the woman chronically infected with *T. gondii* [109] also would be expected to substantially reduce or eliminate congenital *T. gondii* infection, although no data rigorously demonstrating this effect have been provided.

The significance of *T. gondii* infection as a cause of abortion has been a subject of considerable conjecture among workers in this field throughout the world [110,111]. A detailed review of this subject was presented in the first two editions of this book [92,112]; it is omitted from the present edition because no new data are available.

## Transmission by Ingestion

Whether the mode of transmission consists of infective oocysts or meat that contains cysts, it appears that the natural route of transmission usually proceeds from animals (and contaminated soil or water) to humans by way of ingestion.

### Meat

In 1965, Desmonts and colleagues in Paris published what appears to be definitive evidence in favor of the meat-to-human hypothesis [113]. They found that among children in a French hospital, antibodies to *T. gondii* developed at a rate five times that in the general population. Because it was the custom in this hospital to serve undercooked meat (mainly beef or horsemeat) as a therapeutic measure, these workers reasoned that this practice explained the higher incidence of infection among this hospitalized population. To test this hypothesis, they added undercooked mutton to the diet and observed that the yearly rate of acquisition of antibody to *T. gondii* doubled. Clinical signs of infection, mainly lymphadenopathy, developed in some of the children. Severe illness was not observed in any of them. Four years later, Kean and colleagues in New York reported a miniepidemic of toxoplasmosis in five medical students [114]. Epidemiologic evidence strongly implicated the ingestion of undercooked hamburgers, which the authors recognized might have been contaminated with mutton or pork, as the source of infection in these cases [115,116].

A number of isolated cases and recent miniepidemics of acute acquired *T. gondii* infection have been reported. Included were at least one case of congenital toxoplasmosis associated with consumption of undercooked venison or preparation of venison (McLeod R, personal observation), another that resulted in significant illness in adults who ingested undercooked lamb (Remington JS, unpublished data) [117], one in which undercooked kangaroo meat resulted in acute infection in 12 adults and a case of congenital toxoplasmosis [118], and another linked to undercooked pork [119]. In regard to venison, a high prevalence of *T. gondii* antibodies has been reported in white-tailed deer in the United States [120,121].

The prevalence rates in various countries indicate that the habits and customs of various populations in regard to the handling and preparation of meat products are an important factor in the spread of toxoplasmosis [122–125].

### Oocysts

Although ingestion of undercooked meat (especially mutton or pork) explained one mode of transmission, such a hypothesis did not explain how herbivorous animals and vegetarian humans became infected. In humans, the prevalence of *T. gondii* antibodies was the same among vegetarian populations (e.g., Hindus) as among meat-eating populations in the same geographic area (e.g., Christians and Muslims in India) [126,127]. A possible explanation was forthcoming when Hutchison and associates [128], and several others working independently [129,130], described a new form of the parasite, the oocyst.

Oocyst formation has been found to occur only in members of the cat family (e.g., domestic cat, bobcat, mountain lion). Cats may excrete up to 10 million oocysts in a single day, and excretion may continue for 2 weeks. Once shed, the oocyst sporulates in 1 to 5 days and becomes infectious; it may remain so for more than 1 year under appropriate conditions (e.g., in warm, moist soil) [131,132]. This form of the parasite may be inactivated by freezing, heating to a temperature of 45° C to 55° C, drying, or treating with

formalin, ammonia, or tincture of iodine. (For further information on the biology of the oocyst, the reader is referred to the works of Frenkel and Dubey [11,133]). Its buoyancy allows it to float to the top layers of soil after rain, a location more conducive to transmission than the deeper soil where cats usually bury their feces. Transport of the oocyst from the site of deposit may occur by a number of vectors. Coprophagous invertebrates such as cockroaches and flies may mechanically carry oocysts to food [134–136]. Earthworms also may play a role by carrying oocysts to the soil surface [28,137,138].

The relative importance of the oocyst versus undercooked or raw meat in transmission of *T. gondii* to humans remains to be defined. Whereas meat appeared to be of primary importance in most areas of the United States, as shown earlier by Etheredge and Frenkel [139], this was not true for other geographic areas and may not be true currently. Epidemics of toxoplasmosis associated with presumptive exposure to infected cats support the importance of this mode of transmission [140–143].

A cluster of cases of *T. gondii* in Panama [142] and another in a suburb of São Paulo, Brazil [144], appear to have been associated with oocyst-contaminated drinking water. An epidemic in Victoria, Canada, also was considered to be associated with oocysts from wild cats in reservoir water. This reservoir was thought to be contaminated with *T. gondii* oocysts excreted by cougars [145].

Illness and deaths of sea otters on the central coast of California have drawn attention to the presence of *T. gondii* in mussels [146,147]. Mussels appear to concentrate oocysts [146] that then can be consumed by the otters. Infections in aquatic mammals indicate contamination and survival of oocysts in seawater [146]. Lindsay and associates [146,148] demonstrated that oocysts can persist in seawater for many months, sporulate, and remain infectious. Kniel and coworkers [149] found that oocysts can persist and remain infective for up to 8 weeks on raspberries and that they also can adhere to raspberries and blueberries. Consumption of fresh produce with *T. gondii* oocysts could thus be a source of transmission to humans. Oocysts excreted by cats can directly contaminate produce and water used for agriculture. An epidemic in a riding stable in Atlanta raises the question of whether dust contaminated with oocysts with aerosolization could contribute to acquisition of oocysts in that setting [150].

### *Milk*

Unpasteurized milk (goat milk has been especially implicated) has been implicated as a vehicle for transmission of *T. gondii* [151–153], but the process of pasteurization would kill all forms of the organism.

### *Chicken and Eggs*

Prevalence of the infection in chickens reflects *T. gondii* strains in their environment because they feed from the ground [154]. Prevalence of *T. gondii* was determined in 118 free-range chickens from 14 counties in Ohio and in 11 chickens from a pig farm in Massachusetts. *T. gondii* antibodies were demonstrated in 20 of 118 chickens (17%) from Ohio and isolated from 11 of 20 seropositive chickens (55%). Parasites were not isolated from tissues of 63 seronegative chickens. Nineteen isolates were genotyped; five were type II and 14 were type III. Dubey et al isolated *T. gondii* from chickens in many countries [145,154]. In certain areas of Brazil, a high prevalence of infection in chickens and young children has been noted [155].

## Other Means of Transmission

### *Blood Transfusion*

Because prolonged parasitemia has been observed during latent toxoplasmosis in experimental animals [156] and in humans with asymptomatic acquired toxoplasmosis [58,157], transfused blood must be considered a potential vehicle for transmission of the infection. Siegal and colleagues described four patients with acute leukemia in whom overt toxoplasmosis developed after they were given leukocytes from donors with chronic myelogenous leukemia [158]. Three of the four patients died. Retrospective serologic analyses suggested that the transfused donor white cells were the source of the parasite. If a pregnant woman is to receive a whole blood transfusion, selection of a donor without antibodies to *T. gondii* is advisable whenever possible. Patients with chronic myelogenous leukemia and high titers of antibody to *T. gondii* should not be used as blood or blood cell donors [159,160].

### *Laboratory-Acquired Infections (Including Infections Acquired at Autopsy)*

A number of cases of toxoplasmosis have been acquired by laboratory personnel who handle infected animals or contaminated needles and glassware [161–165]. We are aware of numerous cases of laboratory-acquired infection with *T. gondii* that have occurred in recent years. At the Palo Alto Medical Foundation laboratory and Stanford University, more than a dozen such instances have been identified. Some cases were in pregnant women (Remington JS, unpublished data). Certainly, this experience indicates that pregnancy is a contraindication to working with *T. gondii* for women who have no demonstrable *T. gondii* antibodies.

One instance has been reported of toxoplasmosis acquired during performance of an autopsy [166].

### *Arthropods*

The data derived from studies of multiple potential insect vectors are negative and inconclusive [11]. Flies and cockroaches may serve as carriers of oocysts (see Fig. 31–2) [134,135,167].

# EPIDEMIOLOGY

## General Considerations

Toxoplasmosis is a zoonosis; the definitive host is the cat, and all other hosts are incidental. The organism occurs in nature in herbivorous, omnivorous, and carnivorous animals, including all orders of mammals, some birds, and probably some reptiles, although in reptiles this suggestion rests solely on interpretation of histologic preparations [168]. In regard to *T. gondii* in cold-blooded hosts, data suggest that natural infection might occur under suitable environmental conditions [169,170].

The organism is ubiquitous in nature, and toxoplasmosis is one of the most common infections of humans throughout the world. In humans, the prevalence of positive serologic test titers increases with age, indicating past exposure, and no significant difference in prevalence between men and women exists in reports from the United States.

Considerable geographic differences exist in prevalence rates. Differences in the epidemiology of the infection in various geographic locales and between population groups within the same locale may be explained by differences in exposure to the two main sources of the infection: the tissue cyst (in flesh of animals) and the oocyst (in soil and drinking water contaminated by cat feces). The high prevalence of infection in France has been attributed to a preference for consumption of undercooked meat [113]. A similarly high prevalence in Central America has been related to the frequency of stray cats in a climate favoring survival of oocysts and to the type of dwelling [131,171]. Of special note are reports of outbreaks of *T. gondii* infections among family members [132,172].

Among studies designed to identify the risk factors for *T. gondii* infection during pregnancy, results from France, Italy, Norway, and Yugoslavia were reported [123,125,173,174]. The conclusions were that ingestion of raw or undercooked meat, use of kitchen knives that have not been sufficiently washed, and ingestion of unwashed raw vegetables or fruits are factors associated with an increased risk. In a recent case-control study from Europe examining risk factors that predispose pregnant women to infection with *T. gondii* [175], the authors concluded that exposure to inadequately cooked or cured meat accounted for approximately 30% to 63% of infections; thus exposure to meat was interpreted to be the main risk factor for pregnant women in Europe. Other risk factors included contact with soil, which apparently accounted for approximately 6% to 17% of infections; travel outside Europe or the United States and Canada also apparently accounted for some infections. Although contact with soil would presumably reflect risk from cat excrement, the authors concluded that direct "contact with cats" was not a risk factor. They also concluded that mode of acquisition for a large proportion of infections (14% to 49%) remained unexplained.

In a recent study [176] exploring risk factors recognized by mothers of infants with congenital toxoplasmosis in the United States between 1981 and 1998, undercooked meat and possible cat excrement exposure, either one or both, were recognized by approximately 50% of the mothers, but the remainder of the mothers could not identify risk factors.

Consumption of meat that had been frozen was associated with a lower risk. Surprisingly, in Naples, Italy, Buffolano and colleagues [125] observed an increased risk associated with consumption of cured pork; this might be related to the fact that in southern Italy, cured pork usually contains only 1% salt to fresh weight, is stored at less than 12° C, and may be eaten within 10 days of slaughter. A pet cat at home was not associated with an increased risk in any of these studies, but cleaning the cat litter box was a significant risk factor among women in the study from Norway [123]. Health education was associated with a lower risk when it was provided using printed educational materials in a book or magazine [173]. This improved efficacy of print (versus oral) information was observed in the past in Saint Antoine Hospital in Paris; the yearly seroconversion rate decreased from 37 per 1000 to 11 per 1000 when explanatory drawings were given to every seronegative pregnant woman.

## Prevalence of *Toxoplasma gondii* Antibodies Among Women of Childbearing Age

Knowledge of the prevalence of antibodies in women in the childbearing age group is important because of its relevance to the strategic approach for prevention of congenital toxoplasmosis. In evaluating results obtained in any serologic survey, the factors noted earlier under "General Considerations" (in "Epidemiology") must be examined, in addition to two potential causes of differences that may not be real: the serologic method used (and its accuracy) for collection of the data and the dates of collection of the sera.

The prevalence rate among pregnant women in Palo Alto has decreased remarkably, from 27% in 1964 and 24% in 1974 to 10% in 1987 and 1998. The prevalence among pregnant women in Malmo, Sweden, has diminished since 1983.

Relevant to the variability in prevalence of infection among populations within a given geographic area are the observations of Ades and associates [177]. They studied the prevalence of maternal antibody in an anonymous neonatal serosurvey in London in 1991. Among women born in the United Kingdom, the seroprevalence was estimated to be 12.7% in innercity London, 7.5% in suburban London, and 5.5% in nonmetropolitan areas. The prevalence in women from India was 7.6%; Africa, 15% to 41%; Pakistan and Bangladesh, 21%; Ireland, 31%; and the Caribbean, 33%. Thus much of the variation between districts might be explained by ethnic group or country-of-birth composition. Recent data from France are available from national surveys performed in 1995 and 2003 for the Direction Genérale de la Santé [178]. The seroprevalence was 54.3% in 1995, with considerable geographic differences, but had declined to 43.8% in 2003. In the 1995 survey, differences also were noted depending on the country of origin: France, 55%; other European countries, 46%; North Africa, 51%; and south Saharan Africa, 40%. A high prevalence (64%) was observed among women practicing, or whose husbands practiced, a "learned profession." In the Paris area, the seroprevalence has decreased from more than 80% in the 1960s to 72% in the 1970s and to 52% in 2003.

Cultural habits with regard to food probably are the major cause of the differences in frequency of *T. gondii* infection from one country to another, from one region to another in the same country, and from one ethnic group to another in the same region. The data just described all reveal a decrease in the prevalence rate of *T. gondii* antibodies in the United States and in Europe during the past 3 decades. This decrease is more striking in countries that had a high prevalence than in those in which it was low. Because meat probably is a main vector

of infection in most developed countries, it seems logical to relate this decrease to a less frequent presence of *T. gondii* in meat, which probably results from improved methods in the way the animals are raised and in the processing of meat [179,180].

Data from one city or single population within that city may not accurately reflect the true prevalence or incidence of infection either in that city or elsewhere. The prevalence of the infection has decreased dramatically in the past 20 years or so but not necessarily in subpopulations, such as Los Angeles Hispanics, Floridians (Haitians), and Salvadorians.

What are the prevalence and incidence of congenital toxoplasmosis (and *T. gondii* infection) in the United States? We have no objective data to answer this question. It should be emphasized that the lack of systematic serologic screening of pregnant women in the United States for acute acquired *T. gondii* infections severely limits our ability to accurately assess the incidence of *T. gondii* infection among pregnant women in different populations and of congenital *T. gondii* infection.

Numerous variables influence whether congenital transmission will occur. Many of these factors are recognized but poorly understood. They include the strain and virulence of *T. gondii*, inoculum size, route of infection, time during gestation, and immunocompetence of the pregnant woman. All of these also pertain to infection of the fetus and its outcome in the newborn thereafter.

## Incidence of Acquired Infection During Pregnancy

### *Estimates from Prevalence Rates: Mathematical Epidemiologic Models*

Once seroconversion occurs, IgG antibodies essentially persist for the life of the affected person. Thus the prevalence of antibodies increases with increasing age and the proportion of uninfected persons decreases. If the hypothesis is accepted that the risk of acquiring *T. gondii* infection from the environment is the same at any age, and if this yearly seroconversion rate is known, the prevalence of antibodies in relation to age and the proportion of seronegative persons in this population at a given age can be computed easily [181]. Consider as an example a population of infants 1 year of age who are not infected and thus are seronegative: If their risk of acquiring *T. gondii* infection is 10% per year (i.e., for a yearly seroconversion rate of 10%), the probability that these infants will still be free of infection (seronegative) is 0.9 at 2 years of age, 0.81 at 3 years of age, 0.729 at 4 years of age, and so on. At age 20, the prevalence of antibodies will be 86.5%, and the proportion of seronegative persons will be 13.5%. The curves shown in Figure 31–4 depict the theoretical antibody prevalence rates, in relation to age, for a fixed yearly seroconversion rate ranging from 0.1% to 20% (representative of possible rates in various locations). The frequency of acquisition of *T. gondii* infection at a given age (the incidence of *T. gondii* infection at that age) is dependent on both the proportion of the population that is seronegative at that age and on the rate of seroconversion. In the example just given, in a population with a 10% yearly seroconversion rate from the age of

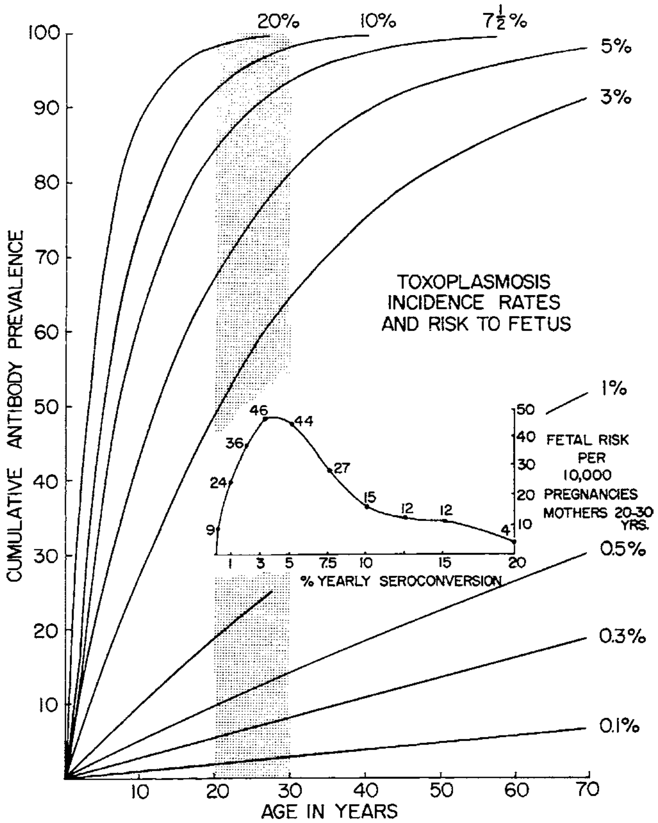

**FIGURE 31–4** Incidence rates in mother and risk to fetus. *(Data from Frenkel JK.* Toxoplasma *in and around us. BioScience 23:343–352, 1973.)*

1 year, the incidence of acquired infection between 20 and 21 years of age will be 10% of 13.5% (i.e., 13.5 per 1000). The balance between the prevalence of immunity due to past infection and the risk of acquiring infection can result in apparently paradoxical findings when one examines the incidence of infection in the young adult. For example, in a population with a yearly seroconversion rate of 5% from the age of 1 year, the prevalence of antibodies will be 62% at age 20 and the incidence of infection between ages 20 and 21 will be 18.9 per 1000. Thus owing to the higher number of seronegatives, a lower constant risk of infection—5% instead of 10% per year—results in a higher frequency of infection acquired by the young adult.

### *Estimates from Prospective Studies of Acquired Infection During Pregnancy and Consequences of Health Education*

During the early 1950s, congenital toxoplasmosis was recognized as a frequent cause of severe neonatal disease in France [65,182], and the feasibility of screening pregnant women for acquired infection during pregnancy was investigated. Serologic screening for *T. gondii* infection during pregnancy became common practice in France and in several European countries during those years. It also should be noted that the life cycle of the parasite was elucidated in the years 1970 to 1971, so that it became possible to instruct women about the mode of transmission of *T. gondii* and how they could avoid

becoming infected. Whereas this health education was carefully attempted in some obstetric centers, no attempt at education was made in others.

The seroconversion rate was significantly lower when health education was attempted, especially when explanatory drawings were provided to seronegative women. Thoumsin and colleagues reported a summary of 22 years of screening for *T. gondii* infection during pregnancy in Liege, Belgium [183]. From 1966 to 1987, 20,901 pregnant women attending the Department of Obstetrics of the C.H.R. of Liege were screened. The numbers of seroconversions observed were 129 (6.4%) among 2027 seronegative women from 1966 to 1975 and 74 (2.8%) among 2601 women from 1976 to 1981. After 1981, prophylactic counseling was provided by a specially trained nurse to all seronegative pregnant women. From 1982 to 1987, the number of seroconversions observed was 48 of 3859 (1.2%). The authors do not state the mean time during which their patients were examined for possible seroconversion. If it was approximately 6 months, these data would suggest that the yearly seroconversion rate was greater than 120 per 1000 before 1975, 56 per 1000 from 1976 to 1981, and 24 per 1000 from 1982 to 1987. These values demonstrate a decrease in the risk of infection quite similar to the decrease observed in Paris, which was described above.

Since 1978, it has been obligatory under French law to test pregnant women for *T. gondii* infection acquired during gestation. The common practice is to perform a test for *T. gondii* antibodies at the first prenatal visit (usually at weeks 10 to 15). The result is reported to the patient; if it is negative, the laboratory that performed the test must send a letter to the woman describing hygienic measures she can practice to avoid infection with *T. gondii*. Serologic testing of seronegative women is repeated monthly until delivery to identify those who seroconvert. If the test performed at the first prenatal visit is suggestive of a recently acquired infection, an avidity assay should be performed. In some instances, a second sample of serum is obtained to attempt to determine whether the infection was acquired during the first few weeks of pregnancy or earlier. One consequence of this procedure is that the surveillance for acquired *T. gondii* infection now encompasses the entire pregnancy, including the first 10 weeks and not solely the last 30 weeks of gestation, as was the case during the first surveys performed in France.

Jeannel and associates [184] reported the results of a survey performed in the Paris area between 1981 and 1983. The prevalence of *T. gondii* antibodies was estimated to be 67.3% with a yearly seroconversion rate equal to 21 per 1000. In 1995, there was a yearly seroconversion rate of 19 per 1000 among patients who received health education. The incidence among primiparous women was twice that of multiparous women. This finding suggests that women who knew they were seronegative because they had been repeatedly tested for infection with *T. gondii* during a previous pregnancy tried to avoid acquiring this infection when they again became pregnant.

The differences in the frequency of *T. gondii* infection from one country to another can be illustrated by the differences in the incidence rates and in the prevalence rates. As an example, the yearly seroconversion rates calculated from the data from Norway [84] are nearly eight times lower than those calculated from the data obtained in 1995 in France [178], and the antibody prevalence rate at the age of pregnancy is five times lower in Norway than it is in France. In the Paris area, the yearly seroconversion rate observed during pregnancy was approximately 60 per 1000 during the late 1950s and early 1960s, and it was about 19 per 1000 in 1995. This lower seroconversion rate was observed as early as 1974, however, when instruction became available to pregnant women on how they could avoid becoming infected [185].

The seroconversion rates observed during these relatively recent surveys from France and from Norway can be used to calculate an expected prevalence rate according to the methods discussed earlier [181,186,187]. This calculated "expected" prevalence rate is lower than the observed prevalence rates in both surveys. This finding suggests that the risk of becoming infected with *T. gondii* is lower among pregnant women than in nonpregnant women, perhaps also the result of health care education provided at the first prenatal visit. Thus the timing of providing pregnant women with the appropriate information on prevention of infection with *T. gondii* at the first prenatal visit probably skews results of prospective studies of acquired *T. gondii* infection during pregnancy by selectively reducing the frequency of infection acquired during the second half of pregnancy.

## Prevalence of Congenital *Toxoplasma gondii* Infection

At present, objective data are lacking on the prevalence of congenital *T. gondii* infection or congenital toxoplasmosis for the United States. Because screening of pregnant women in the United States is not systematic, our ability to accurately assess the incidence of *T. gondii* infection among pregnant women in different populations and of congenital *T. gondii* infection is limited. Data from one city or single population within that city may not accurately reflect the true prevalence or incidence of infection either in that city or elsewhere. Although the prevalence of the infection has decreased in some areas of the United States during the past 20 years or so, this is not necessarily the case in subpopulations even in those same areas.

### *Estimates from Studies at Birth or During Infancy*

Estimates from clinical observations and from autopsy findings are based on data derived mainly from older studies [71,72], which underestimated the actual prevalence because congenital infection uncommonly results in stillbirth or neonatal death and frequently is not diagnosed during infancy because of subclinical infection in the infant and delayed occurrence of signs of infection [189,190].

### *Estimates from Serologic Screening of Neonates or Infants*

The Commonwealth of Massachusetts began screening newborn sera in January 1986 to determine the incidence of congenital *T. gondii* infection. Newborn blood specimens

are collected on filter paper and used to test for IgM antibodies by the sensitive IgM enzyme-linked immunosorbent assay (ELISA). From 1986 to 1999, 93 infants were detected who had IgM *T. gondii* antibodies, reflecting an incidence of approximately 1 in 12,000 births or perhaps 1 in 6,000 births if the sensitivity of the IgM test was 50% as found for some other IgM tests for newborn sera [191]. Although a careful follow-up evaluation was not performed for all seronegative infants, it is known that the diagnosis was missed in at least six infants in whom IgM antibodies were not detected but who were referred by local physicians. In one of these later-diagnosed children, *T. gondii* was isolated from cerebrospinal fluid; the infection was suspected on clinical grounds in this child, who was born prematurely with hydrocephalus, cerebral calcifications, and bilateral chorioretinitis. Thus this reported incidence is lower than the actual incidence despite the sensitivity of the method used to detect IgM antibodies of *T. gondii*. Nevertheless, if as many as 50% of cases were missed (which is unlikely) with the methodology used by the New England Regional Screening Program, an incidence of 1 per 10,000 births is strikingly different from the incidence of 1.3 per 1000 reported by Kimball and coworkers in 1971 from a prospective screening study of pregnant women in New York City [74]. With the discovery of the importance of detecting IgA and IgE antibodies (see "Diagnosis" section) in the newborn, serologic studies of newborns such as those being performed in Massachusetts should detect a higher percentage of infected infants.

Even if the prevalence of congenital infection is underestimated, however, the present data (at least from Massachusetts) suggest that the rate has significantly decreased during the last 2 decades in some populations in the United States [188]. This decrease in the prevalence rate of congenital *T. gondii* infection parallels the historical decrease in antibody prevalence rate observed in the adult. This would be expected from the epidemiologic models discussed earlier; in a population in which the seroprevalence rate was rather low (well below 50% in the adult, as it is in the United States), a decrease in the risk of acquiring infection immediately results in a decrease in the incidence of acquired infection in women in the childbearing age group.

The Danish Congenital Toxoplasmosis Study Group reported results of their feasibility study to determine the prevalence of the infection among live neonates and the maternofetal transmission rate in infected mothers who had received no treatment [192]. Secondarily, they assessed the feasibility and acceptability of neonatal screening using *T. gondii* IgM antibody testing on samples from phenylketonuria (PKU) cards. They reported a surprisingly low maternofetal transmission rate of 19.4% and estimated that a neonatal screening program based on detection of IgM *T. gondii* antibodies using PKU cards alone would identify 70% to 80% of cases of congenital toxoplasmosis; however, not all pregnancies and infants in their study were thoroughly evaluated, thus making the accuracy of this figure uncertain. Based on these findings, a two-step newborn screening program was initiated in Denmark in 1999. PKU card samples were screened for *T. gondii* IgM antibodies, and reactive samples were then evaluated by specific IgG, IgM, and IgA antibody testing. Screening between 1999 and 2007 identified 55 cases of congenital infection (1/4780); 12 of 47 infected infants had retinochoroidal and/or intracranial lesions. This screening program was terminated in 2007 because the incidence was lower than expected and they interpreted the high incidence of new retinal lesions in the first years of life following 3 months of treatment as lack of treatment efficacy, thus leading them to conclude that the program was not cost effective [Nielsen H, personal communication to R McLeod, 2010 and manuscript in press]. Whether outcome would have been more favorable and the conclusions different if these children had been treated for 1 year postnatally as is done in the US NCCTS studies (see section US National Collaborative Chicago-based treatment study below) is not known [193].

## Effects of Systematic Screening of Pregnant Women at Risk on the Prevalence of Congenital *Toxoplasma gondii* Infection and of Congenital Toxoplasmosis

The purpose of the first attempts at systematic serologic screening was to identify pregnant women at risk, to try to prevent congenital toxoplasmosis or, if such infection was present, to allow for early instigation of treatment. Once the life cycle of the parasite was elucidated, primary preventive measures were possible through education of seronegative women (see "Prevention" section and Table 31–51). This is now currently done in several European countries and has proved moderately effective, as judged by the data discussed earlier; acquired *T. gondii* infection during pregnancy apparently is three times less frequent in France than it would be were no information provided to seronegative pregnant women in regard to the sources of infection and how they may reduce their risk of acquiring the infection. This estimation is very close to the conclusions of Foulon and colleagues [194], who calculated that in Brussels primary preventive measures reduced the seroconversion rates during pregnancy by 63%. Even better results are possible, however. One critical point is the time at which this education is provided. In most cases, this intervention occurs during the first prenatal visit, at approximately the tenth week of pregnancy. This timing does not reduce the number of infections acquired during the first 10 weeks of gestation or the number of seroconversions that occur within 2 weeks after the first prenatal visit because women whose seroconversion occurs at this time probably were in the initial stage of the infection (during which parasitemia occurs before antibodies become detectable in the serum) at the time they received the instruction. Thus the results of such an education program can only be a reduction in the number of infections that occur later during pregnancy. Because late acquired infections are those for which the rate of congenital transmission is the highest (resulting primarily in subclinical cases), it is understandable that in addition to a lower number of infections acquired during gestation, health education, if provided at first prenatal visit at about the tenth week of pregnancy, should result in a lower rate of transmission

than observed in the previous surveys performed before the means by which *T. gondii* is horizontally transmitted to humans was known. In addition, the proportion of infected fetuses with the more severe form of congenital toxoplasmosis might be higher unless treatment during gestation is effective in the infected fetus. Health education, although useful, will not benefit those women who contract *T.gondii* infection during pregnancy from unrecognized sources which cannot be avoided. This appears to occur relatively commonly in the U.S. and in epidemics in North America (McLeod, Boyer and colleagues, unpublished observations 2010).

In France, congenital toxoplasmosis was the most frequent fetopathy in the years 1950 to 1960. For example, in this period, several cases of congenital toxoplasmosis were diagnosed each year among approximately 1000 premature infants admitted annually to l'Hôpital de l'Institut de Puériculture de Paris. In 1957, for instance, 7 cases were diagnosed among 1085 newborns. In the same hospital, however, only two cases have been observed between 1980 and 1990. Within 40 years the pediatrician has been witness to a dramatic change in the presenting signs of the disease (Couvreur J, written communication to Remington JS, 1998). In the past, patients were referred to the specialized toxoplasmosis clinic in Paris because they had clinical symptoms or often severe signs that suggested congenital toxoplasmosis. For instance, in a group of 147 neonates or infants with congenital *T. gondii* infection studied between 1949 and 1960, 62.5% had signs of central nervous system (CNS) involvement (with hydrocephalus in two thirds of the patients), and 32.5% had retinochoroiditis without clinical evidence of CNS involvement. Despite their being asymptomatic, most patients now attend the specialized clinic because they are suspected of having, or are diagnosed as having, congenital *T. gondii* infection. Congenital *T. gondii* infection is subclinical and remains subclinical in a majority of them. For example, congenital infection remained subclinical in 166 of 234 infants (71%) observed between 1984 and 1992. In this group, 60 of 234 (26%) had a retinal scar but no CNS involvement; CNS involvement with or without hydrocephalus was present in 8 of 234 (3%) of these infants. At present, severe neurologic or ocular involvement, or both, is observed only among infants born to women in the following patient groups: patients referred from foreign countries where screening is not performed during pregnancy (e.g., Morocco, Algeria, United Kingdom), mothers who for any reason were not screened during pregnancy, mothers who were immunodeficient, and mothers who were erroneously considered to be immune. With these exceptions, in which the clinical status may be considered abnormal (see "Chronic Maternal *Toxoplasma* Infection"), prenatal screening for maternal *T. gondii* infection during pregnancy appears to be an effective preventive measure for congenital toxoplasmosis in France, although the efficacy of this approach has not been formally tested in randomized controlled trials (see Table 31–5) [195,196].

Based on this evidence, mandatory prenatal screening is officially recommended in five European countries, with monthly testing recommended in France and Italy and every third month testing recommended in Austria, Lithuania, and Slovenia [197]. However, in the absence of evidence from randomized controlled clinical trials that prenatal screening and intervention reduces maternofetal transmission or severity of disease in children who are infected in utero (see section "Prevention"), the value of prenatal or neonatal screening has been questioned by some European authorities [195,197]. Given this uncertainty, in other European countries, where the seroprevalence among pregnant women, the incidence of congenital infection, and the numbers of cases of symptomatic congenital toxoplasmosis appear to be lower than in France, routine prenatal or neonatal screening is not, or is no longer, performed. However, it is acknowledged that the absence of evidence from controlled clinical trials is not evidence for the lack of benefit. For this reason, other authorities, including those in France [196] and in the United States [198,199]—although they agree that carefully designed studies are needed to determine the true benefit— believe that a program of screening, careful counseling, and treatment of the pregnant woman who acquires infection during pregnancy is appropriate. This is particularly true in countries such as Brazil, where the incidence of severe, symptomatic congenital toxoplasmosis appears to be much greater than in Europe and North America, perhaps reflecting the greater prevalence in Brazil of more virulent type I and atypical strains of *T. gondii* [200].

# PATHOGENESIS

## Factors Operative During Initial Infection

### *Genetics and Virulence of Toxoplasma gondii*

Genetics of the parasite appear to influence outcome of the maternal infection (R. McLeod and colleagues, unpublished observations 2010). Also, the inoculum size influences the outcome of sporozoite infections in animal models (Dubey, personal communication to R McLeod, 2010) and it is likely that this is also true in human infections.

Not all *T. gondii* parasites are genetically identical. There are three clonal, archetypal lineages called type I, II, and III. Parasites within a lineage are genetically similar. Each lineage has distinct properties in cell culture systems and elicits different pathology in animal models.

Lehman and colleagues (2006) state that their findings suggest that *T. gondii* originated in South America, and that an early variant parasite was carried to Europe from South America, where it evolved into the archetypal type II lineage parasite. Archetypal clonal type II parasites currently cause the preponderance of *T. gondii* infections in Austria [201], France [202], and Poland [203]. There are also genetically variant or "atypical" parasites. Atypical *T. gondii* isolates have been found in Brazil along the Amazon and its tributaries, but have also been identified in other parts of the world, including the United States and Canada.

In a study by Ajzenberg and associates [204] of clonal types of isolates of *T. gondii* in France between 1987 and 2001, almost all (85% in the whole series, and 96% in 57 consecutive isolates from a laboratory in Limoges and a laboratory in Paris) of 86 congenitally infected children had clonal type II parasites. Type I and atypical

isolates were not found in cases of asymptomatic or mild congenital toxoplasmosis. Three isolates with atypical genotypes, which were virulent in mice, were associated with severe congenital infection. In four cases, *T. gondii* was isolated only from the placenta, the infant was not infected, and all four were of clonal type I. Type II isolates occurred in persons with different levels of severity in their signs and symptoms. The main factor influencing severity was reported to be time of acquisition of the infection during gestation. This finding contrasts with that in a small series from Spain (where serologic screening during gestation is not the standard of care, as it is in France) in which all isolates were of clonal type I [205].

In a separate study by Romand [206], clonal types of parasites were not included in their analysis. Nonetheless, the highest amounts of parasite DNA detected in amniotic fluid by PCR assay were associated with the most severe disease in the newborn and most often were related to time in gestation when the infection was acquired (as discussed in "Polymerase Chain Reaction Assay" under "Diagnosis"). It is unclear at present whether any relationship exists between a specific clonal type(s) and either transmission or severity of the infection in the newborn or progression of disease in the congenitally infected infant.

In Brazil, atypical I/III recombinant parasites have been identified that appear to have different biologic behavior in mice and cause far more prominent eye infections in older children and adults [207,208]. Sixty percent of Brazilian children younger than 10 years of age in Minas Gerais state have serologic evidence of infection [155,207,209,210]. Eighty percent of adults are seropositive, and 20% of these have recurrent eye disease [209]. The greater prevalence of type I and atypical lineage *T. gondii* may also be an important factor in the greater severity of progressive eye disease during and following treatment of infants and children with congenital toxoplasmosis in Brazil [200]and Colombia [211,212]. However, severe congenital disease is not restricted to type I and atypical lineage parasites: archetypal type I, type II, and atypical parasites can cause both mild and severe congenital disease in the fetus and newborn infant and disease in older children and adults [202,213–215].

## Host Genetics

Interactions of parasite genetics and host genetics are important in outcomes as well [200,216–218]. The frequency of the human leukocyte antigen (HLA) class II gene DQ3 was found to be increased in infants with congenital toxoplasmosis and hydrocephalus relative to the frequency of this gene in the U.S. population or in infants with congenital toxoplasmosis who did not have hydrocephalus [216,219]. Of interest is that this unique frequency of DQ3 also was noted to be a genetic marker of susceptibility to development of toxoplasmic encephalitis in patients with AIDS [219]. HLA class II DQ genes function in transgenic mice to protect against brain parasite burden. DQ1 protects better than DQ3. This observation is consonant with the observation that the DQ3 gene is more frequent in infants with congenital toxoplasmosis with hydrocephalus than in those without hydrocephalus, and than in the U.S. population [219].

Alleles of the collagen gene *col2a*, variants of which are associated with a genetic eye disease called Stickler disease, and of the lipid transporter gene *abc4r*, variants of which are associated with macular disease and hydrocephalus in a rat model, were associated with risk for eye disease and eye and brain disease, respectively, in children with congenital toxoplasmosis [216]. There was a parent of origin effect suggesting that epigenetic factors are also involved. It has also been demonstrated recently that in addition to these genes, alleles of TLR9, P2x7r, and ERAAP2 are associated with susceptibility to and manifestations of human congenital toxoplasmosis [219–223].

## Role of Cells and Antibody

After local invasion (usually in the intestines), the organisms invade cells directly or are phagocytosed. They multiply intracellularly, causing host cell disruption, and then invade contiguous cells. Whereas human monocytes and neutrophils kill the vast majority of ingested *T. gondii* organisms, tachyzoites survive within macrophages derived in vitro from peripheral blood monocytes [224–226]. Data have shown that human peritoneal and alveolar macrophages kill *T. gondii* [227]. Cytotoxic T lymphocyte-mediated lysis of *T. gondii*-infected target cells did not lead to death of the intracellular parasites, however, indicating that intracellular *T. gondii* remains alive after lysis of host cells by cytolytic T cells [228,229]. The presence of persistent parasitemia observed in humans [58] and animals [230,231] can best be explained by the existence of intracellular parasites in the circulation.

*T. gondii* invades every organ and tissue of the human host except non-nucleated red blood cells, although evidence indicates that invasion of these cells may occur as well [232]. Termination of continued tissue destruction by *T. gondii* depends both on the development of cell-mediated immunity and on antibodies. Continued destruction may occur in those sites where ready access to circulating antibodies is impeded (e.g., CNS, eye). Despite the ability of antibodies in the presence of complement to kill extracellular *T. gondii* effectively *in vitro*, the intracellular habitat of this protozoon protects it from the effects of circulating antibodies.

Cyst formation can be demonstrated as early as the eighth day of experimental infection [42]. Cysts persist in multiple organs and tissues after immunity is acquired, probably for the life of the host.

The ability of the pregnant woman to control multiplication and spread of *T. gondii* depends not only on specific antibody synthesis but also on the time of appearance of cell-mediated immunity. In addition to the immunosuppression associated with pregnancy itself, cell-mediated immunity, at least as measured by antigen-specific lymphocyte transformation, may not be demonstrable for weeks or even months after acute infection with *T. gondii* in humans [233,234]. Although the importance of cellular immunity in the control of the initial acute infection in humans has not been defined, it is likely, from what is known about the immunology of toxoplasmosis in animal models [21,22] and studies with human immune cells [235–237], that cell-mediated immunity plays a major role. Susceptibility alleles of genes specifying innate and adaptive immunity also support this. The helper T-cell type 2 ($T_H2$) bias

(toward humoral immunity and away from cellular immunity) established during normal gestation may compromise successful immunity against *T. gondii*, which requires a strong $T_H1$ response. In addition, it has been proposed that a strong $T_H1$ response against *T. gondii* may overcome the protective $T_H2$ cytokines at the maternal-fetal interface and result in fetal loss [238,239]. For a discussion of the immunoregulation of *T. gondii* infection and toxoplasmosis, the reader is referred to other sources [22,110,240–243].

### Reinfection

Although survival from the acute stages of the initial *T. gondii* infection usually results in resistance to reinfection, the immunity associated with the chronic (latent) infection is only relative. Immunity to *T. gondii* in mice protects against but does not necessarily prevent reinfection [244–249]. Mice immunized with one strain of *T. gondii* and subsequently challenged with another strain have both strains encysted in their tissues. Reinfection may also be responsible for the rare human cases of apparent transmission from a chronically infected immunocompetent mother to her fetus [97,250,251]. Consistent with this possibility is a recent report, which suggested that infection by an atypical strain during pregnancy in a mother previously infected by an archetypal strain may result in infection in the fetus [252]. Disseminated congenital toxoplasmosis was observed in a newborn infant of an apparently immunocompetent mother who had evidence of infection before conception, and who likely became reinfected when she ingested raw horsemeat, likely imported from South America, during her pregnancy. This clinical occurance is exceptionally uncommon in France and therefore raised the possibility of the second infection being caused by a highly virulent *Toxoplasma* strain. The parasite isolated from the peripheral blood of her newborn infant was found to have an atypical genotype, which is very uncommon in Europe but had been described in South America. The investigators tested the hypothesis that reinfection may occur with a different genotype by using an experimental mouse model, which confirmed that acquired immunity against European *Toxoplasma* strains may not protect against reinfection by atypical strains acquired during travel outside Europe or by eating imported meat. With international travel and globalization of markets that involves products from Central and South America, and other continents being distributed throughout the world, the prior observation that once infected a pregnant women does not reacquire parasites that could be transmitted to her fetus may not always be accurate in the future.

## Factors Operative During Latent Infection

### Cyst Rupture

Factors that influence tachyzoite and bradyzoite interconversion are critical to understanding the pathogenesis of recrudescent infection.

Histologic evidence suggesting that cyst rupture concurs in humans has been reported [244,247]. In the brains of chronically infected mice, it is not unusual to find large and small cysts close together, suggesting the possibility that cyst rupture or "leakage" of bradyzoites has caused the satellite cysts [253]. It is not clear whether the satellite cysts are the result of cyst rupture or whether they simply developed at the same time as did the larger cysts in the same area.

Organisms that are intracellular and located within cysts are protected from antibody and cell-mediated immunity. Changes in the host cell membrane that may occur at the time of infection might predispose the infected cell to disruption by lymphokine-activated killer cells [22,236]. Cyst rupture would lead to release of viable organisms that can result in significant tissue damage.

### Persistence of "Active" Infection

Frenkel has suggested that cyst rupture is responsible for underlying persistent immunity and antibody and that the encysted form of the organism causes localized or generalized relapse [11]. A persistent parasitemia has been demonstrated not only in laboratory animals [156,231,254] but also in humans [158,255,256]. In addition, a constant antigenic stimulus has been suggested to account for the persistence of *T. gondii* antibodies, which may remain at high titers for years after the acute infection and at lower titers for the life of the infected host. Antigen-specific lymphocyte proliferation has been demonstrated in persons who had acquired the infection as long ago as 30 years previously [234]. Another observation pointing to the persistence of active infection during chronicity in rodents is that despite having high levels of neutralizing antibody titers, hypergammaglobulinemia [257,258], and resistance to challenge with an ordinarily lethal dose of *T. gondii*, laboratory rats and mice chronically infected with *T. gondii* can transmit the organism to their offspring transplacentally (see "Transmission" section) [230,259].

### "Immunologic Unresponsiveness" to Toxoplasma gondii Antigens

Results of studies in laboratory animals suggest that the maternal IgG antibody may inhibit formation of antibodies to *T. gondii* in the fetus [260].

The observation that *T. gondii* induces expansion of the particular V region, Vδ2, of the γδ T-cell response in acquired infection [261,262] led Hara and associates to examine $V\delta2^+$ γδ T-cell tolerance in infants with congenital *T. gondii* infection [263]. Important in this regard is the observation by Subauste and colleagues [237] that γδ T cells produce IFN-γ, a major mediator of resistance against *T. gondii* [264]. Hara and associates [263] noted that $V\delta2^+$ γδ T cells were anergic with or without clonal expansion during the newborn period in two infants with the congenital infection. Clonal expansion of Vδ2 was not observed to be associated with T-cell response downregulation, and no deletion of $V\delta2^+$ γδ T cells was observed. T-cell anergy was noted in the infants at the age of 1 month, and *T. gondii*-specific anergy was noted at 5 months.

Cord blood of infants with congenital toxoplasmosis has been reported to have increased numbers of $CD45RO^+$ T cells [265]. In the study by Hara and associates, most of the $CD45RO^+$ T cells were γδ T cells, and these T cell levels were not always elevated, especially in an infant with severe disease in the newborn period [263]. In their study, despite persistent αβ T-cell

unresponsiveness in two infants with congenital toxoplasmosis, γδ T cells became reactive to live *T. gondii*-infected cells and produced IFN-γ after the infants reached 1 year of age.

*Toxoplasma*-specific memory CD4+ T-cell responses may also be delayed in their appearance in congenital toxoplasmosis and may not be detectable until weeks or months after birth. McLeod and colleagues found that lymphocyte proliferation in response to *Toxoplasma* antigens, which detects responses by CD4+ T cells, was below the limit of detection in 11 of 25 congenitally infected infants (usually those with the most severe manifestations) with congenital toxoplasmosis younger than 1 year of age [266]. The mechanism(s) for this absence of response and its restoration by 1 year of age remain to be determined. Furthermore, even when lymphocyte proliferation responses were first detected in congenitally infected children, production of IL-2 and IFN-γ assayed in parallel often was less than that by cells from adults with postnatal *Toxoplasma* infection. Results consistent with these were reported by another group. Fatoohi and colleagues [267] found that anti-*Toxoplasma* T-cell responses (determined using a different and less standardized assay) were lower in eight congenitally infected infants younger than 1 year of age than in persons with acquired *Toxoplasma* infection and congenitally infected children studied when they were older than 1 year of age. Nonetheless, anti-*Toxoplasma* T-cell responses were detectable in most of the congenitally infants younger than 1 year of age by this assay. Ciardelli and colleagues [268] also found that greater than 90% of congenitally infected infants less than 90 days of age had detectable T-cell proliferation and IFN-γ production in response to *Toxoplasma* antigen. The basis for the differences between these studies is unknown. Nonetheless, these data suggest that antigen-specific CD4+ T-cell responses may develop more slowly or be diminished in some infants with congenital *Toxoplasma* infection.

Other aspects of immunologic unresponsiveness are discussed under "Special Problems Concerning Pathogenesis in the Eye" and in the "Diagnosis" section.

### Special Problems Concerning Pathogenesis in the Eye and Brain

The plethora of data and the controversy that exists regarding immunity and hypersensitivity as they pertain to toxoplasmic chorioretinitis related to congenital toxoplasmosis preclude complete coverage of the subject here. The reader is referred to reviews of the relevant literature by O'Connor and colleagues [269–273] and to related work in the mouse model of congenital ocular toxoplasmosis [269–271,274–276]. Whereas Frenkel has been a proponent of the theory that toxoplasmic chorioretinitis in older children and adults is a hypersensitivity phenomenon [277], O'Connor and colleagues concluded that both the acute and the recurrent forms of necrotizing chorioretinitis are due to multiplication of *T. gondii* tachyzoites in the retina and that release of antigen into the retina of previously sensitized persons does not result in recurrence of the inflammatory response. *T. gondii* antigen and antibody have been detected in ocular fluids in experimental ocular toxoplasmosis [278]. The rapid resolution of inflammation that occurs with antimicrobial treatment in infants, children, and adults with congenital toxoplasmosis [279] suggests that parasite replication and the resulting destruction of retinal tissue causes the eye disease. Support for the role of the parasite per se also comes from studies in which results of PCR assay in samples of vitreous from adults with the acute acquired infection were positive [280,281]. Studies with PCR analysis also demonstrated that parasite DNA may be detected in aqueous fluid [282,283].

Data are not available in humans that clarify whether the pathogenesis of eye disease related to *T. gondii* in young children is the same as or different from that in adults. The immunologic parameters that may or may not operate in each situation constitute a major factor in determining the severity and outcome of eye infection and disease.

Although the peak incidence of chorioretinitis related to congenital *T. gondii* infection usually is between the ages of 12 and 20 years, chorioretinitis may not occur until late in adult life. Crawford and colleagues described a patient in whom the first eye symptoms occurred at the age of 61 years [284]. For the next 9 years, the inflammatory activity in the posterior segment of one eye continued relentlessly, causing pain and ultimately blindness. The severity of the pain necessitated enucleation. Masses of cysts were found in the retina. In such cases, it is impossible to determine whether the primary infection was congenital or acquired. Reports of significant numbers of cases of toxoplasmic chorioretinitis that occurred during the acute acquired infection in adults highlight the difficulties in attributing all of the cases of toxoplasmic chorioretinitis occurring later in life to the congenital infection [285,286].

The unique predilection of *T. gondii* for maculae, brain periaqueductal and periventricular areas, and basal ganglia in congenital toxoplasmosis remains unexplained. In the mouse model of Deckert-Schlüter and associates [287], it is of interest that congenitally infected mice have similar periventricular lesions, unlike in adult mice. It remains to be determined whether this difference is due to immaturity of the fetal immune system, unique interaction of *T. gondii* antigens with the fetal immune system, or development of the fetal brain at the time infection is initiated, or to some combination of these.

## PATHOLOGY

In reviewing the literature on the pathology of congenital toxoplasmosis, it is immediately apparent that the genesis of the natural infection in the fetus is entirely comparable with that observed in experimental toxoplasmosis in animals. The position of necrotic foci and lesions in general suggests that the organisms reach the brain and all other organs through the bloodstream. Noteworthy is the remarkable variability in distribution of lesions and parasites among the different reported cases [288–291]. Age at the time of autopsy is a major modifying factor, but others include the virulence of the strain of *T. gondii*, the number of organisms actually transmitted from the mother to the fetus, the time during pregnancy when

the infection occurred, the developmental maturity of the infant's immune system, and the number of organs and tissues carefully examined. After the appearance of early reports of cases of congenital toxoplasmosis, the prevailing impression was that the infection manifested itself in infants mainly as an encephalomyelitis and that visceral lesions were uncommon and insignificant. This view reflected the observation of a marked degree of damage to the CNS without a comparable degree of extraneural involvement in these infants. In some cases, however, extraneural lesions are severe and may even predominate [6,291,292]. Thus at autopsy, in some cases only the CNS and eyes may be involved, whereas in others wide dissemination of lesions and parasites may be noted. Between these two extremes are wide variations in the degree of organ and tissue involvement, but the CNS is never spared. The clinical importance of lesions in the CNS and eye is magnified by the limited ability of these tissues to regenerate, compared with the remarkable regenerative capacity of other tissues in the body. Active regeneration of extraneural tissues may be observed even in the most acute stages of infection in the infant [293]. Thus in extraneural organs, residual lesions may be so slight and insignificant that they are easily overlooked. In the CNS and eye, on the other hand, the lesser ability of nerve cells to regenerate leads to more severe permanent damage [293].

The presence of *T. gondii* in the cells lining alveoli and in the endothelium of pulmonary vessels led Callahan and coworkers to suggest that aspiration of infected amniotic fluid in the lungs may be a route of entry of the organism into the fetus [288]. That infection by this route may occur cannot be disputed. The diffuse character of the lung changes contrasts with the more focal lesions found in other organs and tissues. Zuelzer pointed out that this difference may be due to the position of the lungs in the route of circulation. Before dissemination to other tissues of the body all blood with parasites entering the venous circulation must first pass through the alveolar capillaries [293]. Thus the lungs are exposed to more parasites than any other single organ.

## Placenta

The first description of *T. gondii* in placental tissues was by Neghme and coworkers [63]. Subsequently, a number of similar observations have been made [62,64,294–296]. Evidence for the likelihood of the hematogenous route of spread of *T. gondii* to the placenta is supplied by the fact that groups of tachyzoites can be found widely dispersed in the chorionic plate, decidua, and amnion, and organisms have been observed in the placental villi and umbilical cord without associated significant lesions (Fig. 31–5) [61–63,297–299]. The first description of the histopathologic features of a *T. gondii*-infected placenta of a woman with AIDS was by Piche and colleagues in 1997 [300]. The woman experienced a spontaneous abortion associated with fever and *T. gondii* pneumonia.

In five cases studied by Benirschke and Driscoll, the most consistent findings in the placentas were chronic inflammatory reactions in the decidua capsularis and focal reactions in the villi [296]. The lesions appeared to be

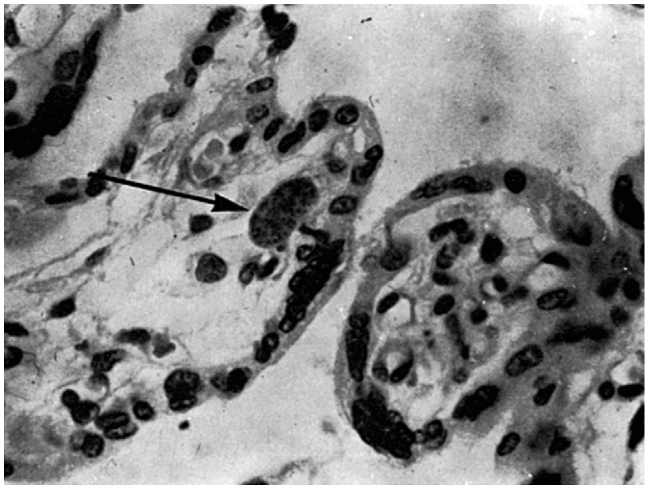

**FIGURE 31–5** *Toxoplasma* cyst in the placenta of an infected fetus (*arrow*).

more severe in infants who died soon after birth. Villous lesions develop at random throughout the placenta. Single or multiple neighboring villi with low-grade chronic inflammation, activation of Hofbauer cells, necrobiosis of component cells, and proliferative fibrosis may be seen. Although villous lesions frequently are observed in placental toxoplasmosis, histologic examination of these foci does not reveal parasites; they occur in free villi and in villi attached to the decidua. Lymphocytes and other mononuclear cells, but rarely plasma cells, make up the intravillous and perivillous infiltrates. The decidual infiltrate consists primarily of lymphocytes. Inflammation of the umbilical cord is uncommon. When fetal hydrops is present, the placenta also is hydropic.

The organism is seen mainly in the tissue cyst form and may be present in the connective tissues of the amnionic and chorionic membranes and Wharton jelly and in the decidua. Benirschke and Driscoll observed one specimen from which the parasite was isolated in which contiguous decidua capsularis, chorion, and amnion contained organisms [296,294]. In a retrospective histologic examination of 13 placentas of newborns with serologic test results suggestive of congenital *T. gondii* infection, Garcia and associates observed organisms that had the morphology of *T. gondii* tachyzoites in four cases [301]. Of interest is that in 10 of their cases, on gross examination, the placenta was found to be abnormal, suggesting the diagnosis of prolonged fetal distress, hematogenous infection, or both.

In some cases, the diagnosis was made initially from examination of the placenta [61,302]. Altshuler made a premortem diagnosis by noting cysts in connective tissue beneath the amnion in a very hydropic placenta [302]. The fetal villi showed hydrops, an abundance of Hofbauer cells, and vascular proliferation. Numerous erythroblasts were present within the vessels of the terminal villi.

Elliott described lesions in a placenta following a third-month spontaneous abortion of a macerated fetus [295]. The placenta showed nodular accumulations of histiocytes beneath the syncytial layer. In villi that had pronounced histiocytic infiltrates, the syncytial layer was

raised away from the villous stroma, and the infiltrate had spilled into the intervillous space. Disruption of the syncytium was associated with coagulation necrosis of the villous stroma and fibrinous exudate. Both encysted and free forms of *T. gondii* were present in the areas of histiocytic inflammation, in the zones of coagulation necrosis, and in the villi without either necrotizing inflammation or syncytial loss. The location of the organisms varied, but they seemed to be concentrated at the interface between the stroma and the trophoblast. This aggregation of histiocytes and organisms at the stroma-trophoblast interface suggested to Elliott that this is a favored site of growth for the parasite.

## Central Nervous System

In infants who die in the newborn period, the severity of the cellular reaction in the leptomeninges of both brain and spinal cord reflects the amount of damage done to underlying tissue. The pia-arachnoid overlying destructive cortical or spinal cord lesions shows congestion of the vessels and infiltration of large numbers of lymphocytes, plasma cells, macrophages, and eosinophils. This type of change is particularly noticeable around small arterioles, venules, and capillaries. Complete obliteration of the gyri and sulci may be noted; the line of demarcation between the pia-arachnoid and brain substance is obscured. Parasites frequently are found within intimal cells of the arterioles, venules, and capillaries [288].

In the cerebral hemispheres, brainstem, and cerebellum, extensive diffuse and focal alterations of the parenchymal architecture are seen (Figs. 31–6 and 31–7) [56,288,293,303,304]. The most characteristic change is the extensive necrosis of the brain parenchyma due to vascular involvement by lesions. The lesions are most intense in the cortex and basal ganglia and at times in the periventricular areas; they are marked by the formation of glial nodules [56], which Wolf and coworkers referred to as characteristic miliary granulomas [304]. Necrosis may progress to actual formation of cystic areas, which have a homogeneous eosinophilic material at the center of the cyst cavity. At the periphery of these cystic areas, focal calcification of necrotic, individual nerve cells may be evident. Calcification within zones of necrosis may be extensive, with the formation of broad bands of calcific material involving most of the cortical layers, or it may be scattered diffusely throughout the foci of necrosis. Calcium salts are deposited in coarse granules or in finely divided particles, which give the appearance of "calcium dust." Many cells become completely calcified, whereas others contain only a few particles of finely divided calcium. Some pathologists have suggested that the *T. gondii* organisms themselves become encrusted with calcium salts [5,293]. (Cells containing fine particles of calcium also are observed in cytomegalovirus infection of the fetus or newborn and may be mistakenly construed as evidence of *T. gondii*.) The extent of calcification appears to depend on the severity of the reaction and the duration of the infection [288]. *T. gondii* tachyzoites and cysts are seen in and adjacent to the necrotic foci, near or in the glial nodules, in perivascular regions, and in cerebral tissue uninvolved by inflammatory change (see Figs. 31–6, *D* and 31–7, *D*) [303].

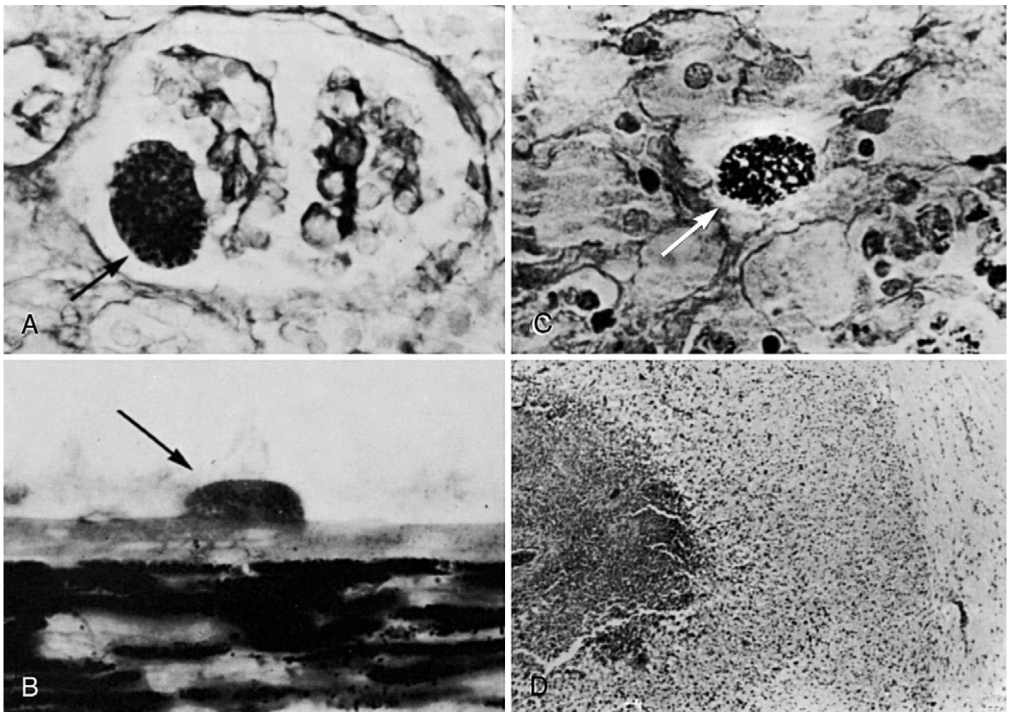

**FIGURE 31–6** **A**, Large cyst (*arrow*) in glomerular space. **B**, *Toxoplasma* cyst (*arrow*) in the retina. Note incomplete pigmentation of the choroid. **C**, *Toxoplasma* cyst (*arrow*) in the cortex of the fetal adrenal gland. **D**, Section of brain showing abscess (*to the left*), normal brain (*on right*), and area of gliosis (*between*). Encysted parasites were abundant at the periphery of these areas. *(From Miller MJ, Seaman E, Remington JS. The clinical spectrum of congenital toxoplasmosis: problems in recognition. J Pediatr 70:714–723, 1967.)*

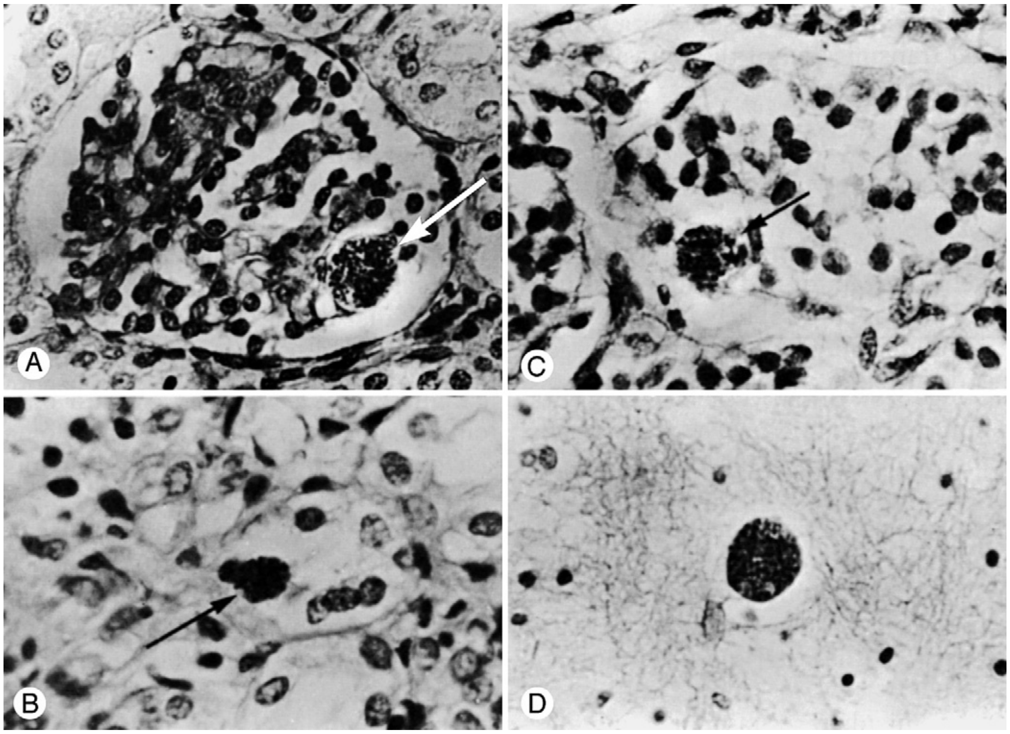

**FIGURE 31–7** **A**, *Toxoplasma* cyst (*arrow*) within a glomerulus. Similar cysts were identified in endothelial cells of the glomeruli and free in the glomerular spaces. **B**, Encysted parasites (*arrow*) in a renal tubule cell. Other cysts were present within lumina of several tubules. **C**, *Toxoplasma* cyst (*arrow*) in immature testicular tissue. **D**, *Toxoplasma* cyst in cerebral cortex. Note lack of inflammatory response. *(From Miller MJ, Seaman E, Remington JS. The clinical spectrum of congenital toxoplasmosis: problems in recognition. J Pediatr 70:714–723, 1967.)*

Hervas and colleagues described an infant who developed progressive drowsiness, a weak cry, and grunting in the newborn period [305]. Computed tomography (CT) revealed cerebral calcifications, multiple ring-enhancing lesions mimicking brain abscesses, and moderate ventricular enlargement. At autopsy, *T. gondii* organisms were seen in the ventricular cerebrospinal fluid. Widespread necrosis and granulomatous lesions with mononuclear infiltrates also were noted.

The degree of change in the spinal cord is extremely variable. It may consist of local infiltration of lymphocytes and plasma cells or, on the other hand, almost complete disruption of the normal architecture, caused by the transformation of the gray and white matter into a mass of necrotic granulation tissue, may be seen. *T. gondii* cysts, which can be identified in the white matter, usually are unassociated with inflammatory reaction.

Periaqueductal and periventricular vasculitis with necrosis is a lesion that occurs only in toxoplasmosis [56]. The large areas of necrosis have been attributed to vascular thrombosis. The necrotic brain tissue autolyzes and gradually sloughs into the ventricles. The protein content of such ventricular fluid may be in the range of grams per deciliter, and the fluid has been shown to contain significant amounts of *T. gondii* antigens [306]. If the cerebral aqueduct of Sylvius becomes obstructed by the ependymitis, the lateral and third ventricles begin to resemble an abscess cavity containing accumulations of *T. gondii* and inflammatory cells [307]. Hydrocephalus develops in such children, and the necrotic brain tissue may calcify and become visible on radiographs. The fourth ventricle may show ulcers and ependymal nodules but is free from periventricular vasculitis and necrosis, apparently as a consequence of adequate drainage of its fluid through the foramina of Luschka and Magendie. The cerebrospinal fluid that communicates with the fourth ventricle often contains several hundred milligrams per deciliter of protein and fewer inflammatory cells than are seen in the lateral ventricle fluid [307]. Frequently, inflammation and necrosis are seen to involve the hypothalamus surrounding the third ventricle. Wolf and coworkers suggested that such lesions in the floor of the third ventricle probably cause the temperature lability observed in infants with congenital toxoplasmosis [304]. Destruction of brain tissue, especially intense periventricular necrosis, rather than obstruction of ventricular passages, appears to account for the development of hydrocephalus in some cases [293,304].

## Eye

The histopathologic features of the ocular lesions depend on their stage of development at the time of the examination; a number of studies describing lesions in the earliest-recognized cases have been published [6,8,308–311], and were reviewed by Hogan in his classic thesis [312]. The description that follows is based on Hogan's summary of his and other cases.

The primary and principal lesions are found in the retina and choroid; secondary changes, such as iridocyclitis and cataracts [311], that occur in other portions of the eye are considered to represent complications of the chorioretinitis. Intraocular inflammation may cause

microphthalmia, owing to arrest in development of the eye, or a secondary atrophy may result in shrinkage of the globe. The frequently reported failure of regression of the fetal pupillary vessels may indicate that an arrest in development occurred.

The inflammation commences in the retina (see Fig. 31–6, *B*), and a copious exudate in the vitreous produces a marked haze. Secondary involvement of the choroid causes marked elevation; small satellite foci are common. After healing, the lesions are atrophic and pale, with a variable amount of pigmentation at the margins.

The organisms first lodge in the capillaries of the inner layers of the retina, invade the endothelium, and extend into adjacent tissues. An intense focal inflammatory reaction results, with edema and infiltration of polymorphonuclear leukocytes, lymphocytes, plasma cells, mononuclear cells, and, in some cases, eosinophils. The reaction results in disruption and disorganization of the retinal layers. Cells are dislocated from the nuclear layers into the adjacent fiber layers. The external limiting membrane may be ruptured, displacing retinal cells into the subretinal space. The inner limiting membrane may also be interrupted, and cells from the inner nuclear layers are then displaced into the adjacent vitreous. Glial tissue, vascular connective tissue, and inflammatory exudate also extend through the interruptions in the inner and outer limiting membranes. In the zones of most acute inflammation, all retinal supporting and neural tissues are completely destroyed. The pigmentary epithelium shows extensive destruction. The retina may detach.

In the healing process, proliferation of the retinal pigment epithelial cells bordering the inflammatory foci occurs. Large lesions cause considerable necrosis and destruction, resulting in marked central atrophy of the retina and choroid. Disorganization of retinal cells has occurred [313].

Inflammation in the choroid is most acute beneath the retinal foci and is rather well demarcated. The Bruch membrane frequently is destroyed, and proliferation of connective tissue into the subretinal space may be seen. Retina and choroid thereby become fixed to each other by a scar. The choroidal vessels usually are engorged and show perivascular infiltration of lymphocytes, plasma cells, mononuclear cells, and eosinophils. Lymphocytes predominate, and both $CD4^{+}$ and $CD8^{+}$ lymphocytes are present [313].

Organisms are present in the retinal lesions and, in general, are most numerous where the lesions are most severe (see Fig. 31–6, *B*). Occasional parasites without an accompanying reaction are observed in relatively normal portions of the retina near the margins of inflammatory foci. The organisms may occur singly or in clusters, free or intracellularly, or in cysts (see Fig. 31–1, *C* and *D*). They are rarely seen in the choroid. They also have been found in the tissues of the optic papilla and in optic nerves associated with inflammatory cells in congenital cases [290,313].

Serofibrinous exudate and inflammatory cells extend into the vitreous through dehiscences in the inner limiting membrane of the retina. The exudate may be accompanied by masses of budding capillaries, and the vitreous becomes infiltrated with granulation tissue.

The optic disk may show papillitis, sometimes associated with optic neuritis and sometimes secondary to inflammation in the adjacent retina or papilledema caused by the hydrocephalus [313]. Leptomeningeal inflammation may be present around the optic nerve.

## Ear

The presence of the parasite in the mastoid and inner ear and the accompanying inflammatory and pathologic changes have been considered to be causes of deafness in congenital toxoplasmosis [288,314]. Also, brainstem involvement affecting auditory nuclei can lead to inability to process auditory input.

## Lungs and Heart

The alveolar septa may be widened, edematous, and infiltrated with mononuclear cells, occasional plasma cells, and rare eosinophils. The walls of small blood vessels may be infiltrated with lymphocytes and mononuclear cells, and parasites may be found in endothelial cells [288]. In many cases, some degree of bronchopneumonia, often caused by suprainfection with other agents, is present. *T. gondii* has been identified in the epithelial cells lining alveoli and within the endothelium of small blood vessels in such cases; in some affected patients, the pneumonic process was considered to be a prominent part of the general disease [288]. Single organisms have been found free in alveoli in the cases described by Zuelzer [293] and Paige and coworkers [6]. Of interest, their pathologic findings are identical to those described for adults in whom the lungs were particularly involved [8]. For a review of this subject in congenital and acquired cases, the reader is referred to the published articles by Couvreur [315] and Pomeroy and Filice [316].

*T. gondii* is almost always found in the heart in the form of cysts in myocardial fibers, accompanied by pathologic changes in the heart muscle. A focal infiltration with lymphocytes, plasma cells, mononuclear cells, and occasional eosinophils is seen. These foci usually do not contain organisms. In the focal areas of infiltration, the myocardial cells may undergo hyaline necrosis and fragmentation. Parasites are found in myocardial fibers in large aggregates and in cysts without any accompanying inflammatory reaction (see Fig. 31–1, *D*). Single parasites often may be present in areas of beginning necrosis and peripherally in larger areas of necrosis [288,293,303]. Extensive calcification of the heart, involving primarily the right ventricle and intraventricular septum, was observed in a 3-hour-old infant and was attributed to congenital toxoplasmosis [288]. Involvement of the heart has been demonstrated in a congenitally infected infant with AIDS who died of pneumocystis pneumonia and toxoplasmosis. Autopsy was limited to cardiac biopsy and revealed marked autolytic changes without evidence of inflammatory reaction or fibrosis. *T. gondii* organisms were identified in the muscle fibers [317].

## Spleen, Liver, Ascites, and Kidney

Marked engorgement of the splenic pulp may be noted, along with erythropoiesis. In general, no significant pathologic changes that could be attributed to direct destruction by the parasite have been noted in the spleen. In

some cases, an eosinophilic leukocytic infiltration has been described [56,293]. Organisms are rarely seen in the spleen.

In most cases, parasites are not identified in the liver, and neither necrosis nor inflammatory cell infiltrations are present. In some instances, in areas of marked hepatocellular degenerative changes do occur but without associated cellular infiltration [56,291,293]. The periportal spaces may be infiltrated with mononuclear cells, neutrophils, and eosinophils. Enlargement of the liver frequently is pronounced and is accompanied by erythropoiesis, as occurs also in the spleen. In a few cases, hepatic cirrhosis has been observed as a sequel to congenital toxoplasmosis [318]. Caldera and coworkers have described calcification in the liver seen both radiologically and at autopsy [319].

Congenital toxoplasmosis was diagnosed by exfoliative cytologic examination of ascitic fluid in a 7-week-old infant born at 38 weeks of gestation. Hepatomegaly and anemia developed shortly after birth, and liver failure and ascites during the first week of life. Because an extensive workup failed to reveal a cause, a paracentesis was performed that revealed tachyzoites both in Wright-stained smear preparations and in electron microscopy sections. This case is reminiscent of that of an adult patient with AIDS in whom the diagnosis of toxoplasmosis was first established on examination of Wright-Giemsa-stained smears of ascitic fluid obtained because of suspected bacterial peritonitis [320].

Numerous foci of hematopoiesis may be seen in the kidney. Focal glomerulitis often has been observed; in such cases, a majority of glomeruli remain intact [288,293]. In fully developed lesions, glomerular tufts undergo massive necrosis, and necrosis of adjacent tubules may be seen. In the earlier stages of the glomerular lesion, some capillary loops are still intact; in others, necrotic areas are observed in the basement membrane and epithelium, and the lumina are occluded by fibrin thrombi. In some of these partly preserved glomeruli, single parasites have been found in cells of the exudate within the capsular space or embedded in the necrotic remains of the capillary loop [293]. *T. gondii* cysts have been found in glomeruli and renal tubules of kidneys in which there were no other associated lesions (see Figs. 31–6, *A* and 31–7, *A* and *B*) [321,322]. In severely affected kidneys, focal areas of necrosis also are found in the collecting tubules in the medulla. The inflammatory infiltrations are predominantly mononuclear, although in some cases, numerous eosinophils also are seen scattered throughout. In 1966, Fediushina and Sherstennikova reported the pathologic findings in the kidneys in nine cases of congenital toxoplasmosis [323]. In three of these cases, distinct changes in the glomeruli were noted, and as described by these investigators, many of the changes appear to resemble those observed in glomerulonephritis from other causes, including streptococcal infection.

In 1972, Wickbom and Winberg reported a case of a 10-week-old boy with congenital toxoplasmosis who developed severe nephritis with the nephrotic syndrome [324]. In that same year, Shahin and associates reported a case of nephrotic syndrome in a 4-month-old infant with congenital toxoplasmosis [325]. Granular and pseudolinear glomerular deposits of IgM, fibrinogen, and *T. gondii* antigen and antibody were demonstrated in the glomeruli of the initial biopsy of renal tissue. After approximately 7 months of treatment, a second renal biopsy showed no evidence of the *T. gondii* antigen-antibody complexes previously noted, but IgM, fibrinogen, and the fourth component of complement (C4) were present. IgG and C3 were not demonstrable in the glomeruli in either biopsy specimen. Light microscopy of the first renal biopsy revealed glomeruli with a diffuse mild increase in mesangial cells and matrix. One glomerulus contained a segmented area of sclerosis that adhered to the Bowman capsule. Other findings included rare foci of tubular atrophy and associated interstitial fibrosis, occasional hyaline casts, focal tubular and interstitial calcification, and prominent tubular hyaline droplets. The second renal biopsy specimen, obtained after treatment with prednisone for 7 months and with pyrimethamine and sulfadiazine for 3 weeks, revealed glomeruli with varying degrees of damage, ranging from total hyalinization to partial collapse and segmental sclerosis. The tubulointerstitial changes were not significantly different from those observed in the first biopsy specimen. The results of electron microscopy also were reported.

## Endocrine Organs

Parasites and numerous foci of necrosis have been identified in the adrenal cortex (see Fig. 31–6, *C*). Similar areas of necrosis have been found in the pancreas [6,288,292,293]. Parasites, usually without associated inflammation, have been found in the pituitary [288,292]. Large clusters of organisms, without accompanying inflammation or necrosis, have been found in the acini of the thyroid gland [6]. In the testes and ovaries, acute interstitial inflammation with focal areas of necrosis are frequently observed [6,56,288,292,293]. Necrosis of the seminiferous tubules with preservation of adjacent units is common, with infiltration with plasma cells, lymphocytes, mononuclear cells, and eosinophils. Parasites often are observed in the spermatogonia of intact tubules (see Fig. 31–7, *C*). Focal hematopoiesis has been observed in the interstitia of these organs.

## Skeletal Muscle

Involvement varies, ranging in degree from parasitized fibers without pathologic changes to focal areas of infiltration or widespread myositis with necrosis. The organisms in parasitized fibers are found beneath the sarcolemmal sheaths. Hundreds of organisms may be present in a single long tubular space in a fiber, and *T. gondii* cysts frequently are seen in muscle fibers. The affected fibers are swollen and lose their striations, but as a rule, no inflammatory reactions are noted. By contrast, focal areas of inflammation and necrosis may be present in areas where only a few parasites or none can be identified. The cellular infiltrate consists mainly of mononuclear cells, but lymphocytes, plasma cells, and eosinophils also are present. In rare instances, focal inflammatory lesions may be found adjacent to heavily parasitized but unbroken muscle fibers [293]. Noteworthy is the description of severe involvement of the extraocular muscles in the case described by Rodney and coworkers [303].

## Thymus

Sarrut observed a hypoplastic thymus in an infant who died of congenital toxoplasmosis at the age of 1 month (personal communication to Desmonts G, 1980). The disease was not diagnosed before autopsy. *T. gondii* organisms were isolated from the brain and heart. The histologic picture in this case was quite different from that described in experimental infection in newborn mice [326] in that in the former, hypoplasia involved both lymphocytes and Hassall corpuscles.

## Skin

Torres found *T. gondii* tachyzoites without formation of lesions in the subcutaneous tissue of one infant [327]. In a case ("case 5") reported by Paige and associates, *T. gondii* organisms were present in the subcutaneous tissue, again with no associated inflammatory lesion or necrosis [6]. No rash was noted in the infant.

## Bone

Milgram described osseous changes in a fatal case of congenital toxoplasmosis [292]. The infant died on day 17, and at autopsy widespread active infection was discovered. The parasite was found in almost all tissues of the body. Large numbers of inflammatory cells were found in the bone marrow, with deficient osteogenesis and remodeling in the primary spongiosa. Intracellular aggregates of *T. gondii* were present in macrophages in the bone marrow.

## Immunoglobulin Abnormalities

Subtle abnormalities have been noted in the development of immunoglobulins in infants with subclinical congenital toxoplasmosis [328]. In several infants, retarded development of IgA for the first 3 years of life and excessive development of IgG and IgM were noted. The latter abnormality also is seen in congenital rubella, cytomegalic inclusion disease, and syphilis. In the *T. gondii*-infected children, the degree of increase in IgG and IgM appeared to be directly related to the severity of the infection.

Oxelius described monoclonal (M) immunoglobulins of the IgG class in the serum and cerebrospinal fluid of three newborns with severe clinical signs of congenital toxoplasmosis [329]. Because these M proteins were found in the sera of newborns but not in the sera of their mothers, Oxelius concluded that the M immunoglobulins were either selectively transferred or synthesized by the newborn. Reports by Van Camp and associates [330] and Griscelli and colleagues [331] suggest that the observation by Oxelius may not be uncommon. Griscelli and colleagues performed a survey of 27 newborns and older infants who had the severe form of congenital toxoplasmosis. In 11 of the infants, M IgG components were noted. These authors concluded that these components were synthesized by the fetus because they could be detected up to 75 days post partum and were absent in maternal serum. They were unable to define any anti-*T. gondii* antibody in isolated M IgG. Absorption of the hypergammaglobulinemic sera with antigens of *T. gondii* resulted in almost complete loss of anti-*Toxoplasma* antibodies detected using the dye test but did not affect the presence of the M component or significantly reduce the immunoglobulin levels. Similar results have been reported in *T. gondii*-infected mice; hypergammaglobulinemia and a condition that appeared to be a monoclonal spike was observed [258]. The underlying mechanism or the cause of the appearance of M components in infants with congenital toxoplasmosis is unknown. M components have also been described in congenital syphilis [332].

## *Toxoplasma gondii*–Cytomegalovirus Infection

A number of reports of dual infection with *T. gondii*–cytomegalovirus have appeared [333–336]. In systematically searching for cytomegalovirus infection among nine autopsies in cases of congenital toxoplasmosis, Vinh and coworkers found these two diseases coexisting in two instances [335]. Sotelo-Avila and associates described a case of coexisting congenital toxoplasmosis and cytomegalovirus infection in a microcephalic infant who died at the age of 15 days [336]. Microscopically, numerous areas of calcification and necrosis and large cells with the characteristic nuclear inclusions of cytomegalovirus were seen. Aggregates of *T. gondii* were found in the cytoplasm of many of the cytomegalic inclusion cells in the CNS, lungs, retina, kidneys, and liver. Maszkiewicz and colleagues described a case of cytomegalic inclusion disease with toxoplasmosis in a premature infant [335].

# CLINICAL MANIFESTATIONS

## Infection in the Pregnant Woman

Because acute acquired *T. gondii* infection in the pregnant woman usually is unrecognized, the infection in such cases has been said to be asymptomatic. A diagnosis of asymptomatic infection is based largely on retrospective questioning of mothers who gave birth to infected infants and requires prospective clinical studies for documentation. Even if signs and symptoms are more frequently associated with the acute infection, they often are so slight as to escape the memory in the vast majority of women.

The most commonly recognized clinical manifestations of acquired toxoplasmosis are lymphadenopathy and fatigue without fever [163,337–339]. The groups of nodes most commonly involved are the cervical, suboccipital, supraclavicular, axillary, and inguinal. The adenopathy may be localized (e.g., most commonly a single posterior cervical node is enlarged), or it may involve multiple areas, including retroperitoneal and mesenteric nodes [340]. Palpable nodes usually are discrete, vary in firmness, and may or may not be tender; there is no tendency toward suppuration. The lymphadenopathy may occasionally have a febrile course accompanied by malaise, headache, fatigue, sore throat, and myalgia-features that closely simulate those of infectious mononucleosis. The spleen [341] and liver [342] also may be involved [343–345]. Atypical lymphocytes indistinguishable from those

seen in infectious mononucleosis may be present in smears of peripheral blood. In some patients, lymphadenopathy may persist for as long as 1 year, and malaise also may be persistent, although this finding is more difficult to relate directly to the infection [346]. An exanthem may be present—it has been described in a pregnant patient [290]. An association of *T. gondii* infection and the clinical syndromes of polymyositis and dermatomyositis has been reported [347–350]. Chorioretinitis occurs in the acute acquired infection, and many such cases have been documented [351–355]. In São Paulo and Minais Gerais, Brazil, retinal disease has been reported to be common in the acute acquired infection [207,210].

## Infection in the Infant

### General Considerations

A diagnosis of congenital *T. gondii* infection usually is considered in infants who show signs of hydrocephalus, chorioretinitis, and intracranial calcifications. These signs, often described as the classic triad [356], were present in the first proven case of congenital toxoplasmosis described by Wolf and colleagues in 1939 [5]. Since this original observation was made, however, they, and other investigators, have seen and described congenitally infected infants who presented with a variety of clinical signs; the clinical spectrum may range from normal appearance at birth to a picture of erythroblastosis, hydrops fetalis, the classic triad of toxoplasmosis, or a variety of other manifestations [356,357]. Thus such wide variation in clinical signs precludes a diagnosis according to strict adherence to a set of specific clinical criteria. Such adherence may lead to misdiagnoses, especially in cases of congenital toxoplasmosis in which the signs mimic those of other disease states. Until the variability in the clinical picture of congenital *T. gondii* infection is appreciated by pediatricians and until the diagnosis is considered more often in infants with mild nonspecific illness, the blindness, mental retardation, and even death related to *T. gondii* infection will continue to go unrecognized.

Congenital *T. gondii* infection may occur in one of four forms: (1) a neonatal disease; (2) a disease (severe or mild) occurring in the first months of life; (3) sequelae or relapse of a previously undiagnosed infection during infancy, childhood, or adolescence; or (4) a subclinical infection. When clinically recognized in the neonate, the infection usually is severe. Symptoms and signs of generalized infection may be prominent, and signs referable to the CNS are almost always present. The neurologic signs frequently are more extensive than might be suspected at first.

In other neonates, neurologic signs (e.g., convulsions, bulging fontanelle, nystagmus, abnormal increase in head circumference) are the major indications of the diagnosis. Such manifestations are not always associated with gross cerebral damage; instead, they may be related to an active encephalitis not yet associated with irreversible cerebral necrosis or to obstruction of the cerebral aqueduct of Sylvius caused by edema or inflammatory cells, or both, rather than to extensive necrosis and irreversible brain parenchymal damage. In these latter infants who receive treatment, signs and symptoms may disappear and development may be normal thereafter.

Mild cases in the neonate usually are not recognized. Identification of the disease has been possible in prospective studies, however, when infants born to mothers known to have acquired *T. gondii* infection during pregnancy are examined. The most frequent signs include isolated chorioretinal scars. Such cases prove that the infection was active during fetal life without causing other detectable damage.

Most children with congenital *T. gondii* infection are thought to have been normal at birth, as signs or symptoms were not recognized and other signs become manifest weeks, months, or years later. Obviously, in many cases this clinical picture is not one of delayed onset of disease but one of late recognition of disease. Nevertheless, it has been possible to verify delayed onset of disease weeks or months or years after birth in children who at birth had no abnormalities that could be related to toxoplasmosis [61,182,328,358]. Disease with delayed onset may be severe and is most frequently seen in premature infants, in whom severe CNS and eye lesions appear during the first 3 months after birth. In the full-term infant with delayed onset of disease, manifestations arise mainly during the first 2 months of life. Clinical signs may be related to generalized infection (e.g., hepatosplenomegaly, delayed onset of icterus, lymphadenopathy); CNS involvement (e.g., encephalitis or hydrocephalus), which may occur after a more protracted period; or eye lesions, which may develop months or years after birth in infants and children whose fundi are checked repeatedly.

Sequelae most often are ocular (e.g., chorioretinitis occurring at school age or adolescence), but in some cases they are neurologic—for instance, convulsions may lead to the discovery of cerebral calcifications or retinal scars. Ocular lesions may recur during childhood, adolescence, or adulthood. In some instances, neurologic relapses (e.g., late obstruction of the aqueduct) have been observed.

Congenital *T. gondii* infection in the newborn in the series from France, and in a study performed in the United States [182,359], most frequently was a subclinical or inapparent infection, not, as had previously been thought, an obvious and fulminant one. In those infants who were clinically normal at birth, the infection was diagnosed by demonstration of persistent serologic test titers. Such asymptomatic infants may suffer no untoward sequelae of the infection, or more often, abnormalities such as chorioretinitis, strabismus, blindness, hydrocephaly or microcephaly, psychomotor and mental retardation, epilepsy, or deafness may develop or become apparent only months or even years later [245,360,361]. Such patients—asymptomatic at birth but demonstrating untoward sequelae later—were noted by Callahan and coworkers in the early 1940s (their cases 3 and 4) [288]. Frequently, neurologic signs or hydrocephalus appears between 3 and 12 months of life [362]. In patients with encephalitic lesions, CNS abnormalities that produce clinical signs rarely develop after the first year (see "Follow-up Studies" later on) [363].

At present, no parameters are available to use in predicting the precise outcome in a newborn with asymptomatic *T. gondii* infection who remains untreated. Hundreds of reports, however, attest to the crippling effects of infection when severe disease is apparent at birth.

**Clinically Apparent Disease.** One of the most complete studies was that of Eichenwald, who in 1947 initiated a study to discover the clinical forms of congenital toxoplasmosis and to determine the natural history of the infection and its effect on the infant [356]. The cases were referred by a group of cooperating hospitals in a systematic and prearranged manner. Sera were obtained from three groups of infants and their mothers. The first two groups consisted of 5492 infants examined because they had either undiagnosed CNS disease in the first year of life (neurologic disease group) or undiagnosed nonneurologic diseases during the first 2 months of life (generalized disease group). The third group consisted of 5761 normal infants. The incidence rates of serologically proven cases in the three groups were 4.9%, 1.3%, and 0.07%, respectively. Of the 11,253 infants studied, 156 had serologically proven congenital toxoplasmosis; 69% were in the neurologic disease group, and 28% were in the generalized disease group. The signs and symptoms in the infants in these two groups are shown in Table 31–10. Approximately one third showed signs and symptoms of an acute infectious process, with splenomegaly, hepatomegaly, jaundice, anemia, chorioretinitis, and abnormal cerebrospinal fluid as the most common findings. The so-called classic triad of toxoplasmosis was demonstrated in only a small proportion of the patients. The fact that 98% of the infants had clinical evidence of infection can be explained by the manner in which the case material was collected for the study. Despite the fact that Eichenwald clearly defined this, his data for years have been misinterpreted to show that all infants with congenital *T. gondii* infection have signs and symptoms of infection, as set forth in Table 31–10. Most of the patients were evaluated over a period from birth to the age of 5 years or beyond. The overall mortality rate was 12% (no significant differences in mortality rate existed between the clinical groups), and approximately 85% of the survivors were mentally retarded. Convulsions, spasticity, and palsies developed in almost 75%, and about 50% had severely impaired vision (Table 31–11). It is noteworthy that deafness, usually attributed to congenital viral infections (e.g., cytomegalovirus infection, rubella), also occurs as a sequel to congenital *T. gondii* infection. The signs and symptoms in this series of patients differ in many respects from those recorded in reports published earlier, owing undoubtedly to the fact that the cases studied by Eichenwald were drawn from a relatively unselected group rather than from a limited survey based on infants tested solely because they showed most of the so-called classic signs of congenital toxoplasmosis.

**TABLE 31–10** Signs and Symptoms Occurring Before Diagnosis or During the Course of Acute Congenital Toxoplasmosis

| Signs and Symptoms | Frequency of Occurrence (%) in Infants with: *Neurologic Disease** (108 Cases) | *Generalized Disease*† (44 Cases) |
|---|---|---|
| Chorioretinitis | 94 | 66 |
| Abnormal spinal fluid | 55 | 84 |
| Anemia | 51 | 77 |
| Convulsions | 50 | 18 |

**Subclinical Infection.** Studies of subclinical infection have been performed in an attempt to determine the following: how often congenital *T. gondii* infection is subclinical; whether it is really subclinical or whether, in fact, initial signs have gone unrecognized; and what the prognosis is for subclinical infection. For information on prognosis, see "Follow-up Studies," later on in this section.

**TABLE 31–12** Data in 10 Newborns with Congenital *Toxoplasma* Infection Identified by the Presence of IgM *Toxoplasma* Antibodies

Alford and colleagues performed a series of studies to determine the medical significance of the subclinical form of congenital *T. gondii* infection [328]. Their serologic screening program (see "Diagnosis" section) was performed in a moderately low-socioeconomic-status urban population in the southern United States, and 10 infants with congenital *T. gondii* infection were detected among 7500 newborns screened (1 proven case per 750 deliveries over a study period of 2.5 years). The findings in the 10 newborns are shown in Table 31–12. Only 1 infant had signs that suggested *T. gondii* infection (hepatosplenomegaly, chorioretinitis, cerebral calcification). Thus nine of the infected infants would have escaped detection were it not for the laboratory screening program. The investigators pointed out that, nevertheless, significant abnormalities were found in this group of newborns with so-called subclinical infection. Half were premature, and the average birth weight of the infected infants, 2664 g, was 349 g less than that of control infants (3013 g). Although no signs or symptoms referable to the nervous system were present in the nine infants, abnormalities in the cerebrospinal fluid were noted in each of the eight infants in whom this examination was performed. Cerebrospinal fluid lymphocytosis (10 to 110 cells per μL) and elevated protein levels (150 to 1000 mg/dL) persisted for 2 weeks to 4 months or more (average, at least 3 months for the group), even in infants who were given treatment in the first 4 weeks after birth. The findings in a severe case and a mild case are depicted graphically in Figures 31–8 and 31–9, respectively. The infant whose data are shown in Figure 31–8 was premature but demonstrated no signs of infection during the neonatal period. The elevated level of cerebrospinal fluid protein

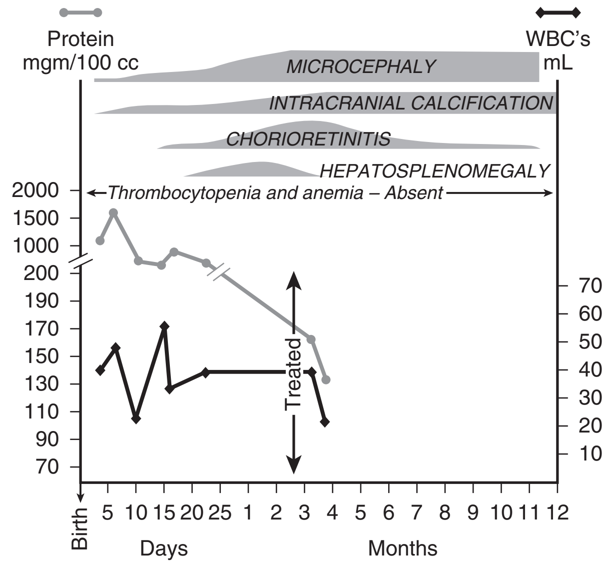

**FIGURE 31–8** Severe form of congenital toxoplasmosis. Protein content and WBC count in cerebrospinal fluid, with clinical findings, over clinical course. *(From Alford CA, et al. Subclinical central nervous system disease of neonates: a prospective study of infants born with increased levels of IgM. J Pediatr 75:1167–1178, 1969.)*

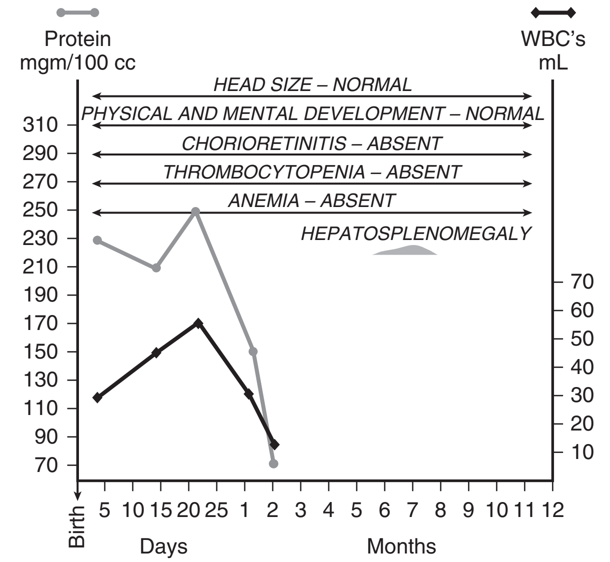

**FIGURE 31–9** Mild form of congenital toxoplasmosis. Protein content and WBC count in cerebrospinal fluid, with clinical findings, over clinical course. *(Data from Alford CA, et al. Subclinical central nervous system disease of neonates: a prospective study of infants born with increased levels of IgM. J Pediatr 75:1167–1178, 1969.)*

suggested severe CNS involvement from birth onward. At 2.5 months of age, retarded growth of the head, generalized intracranial calcification, chorioretinitis, and hepatosplenomegaly first became evident; these abnormalities worsened despite treatment with pyrimethamine and sulfadiazine, which was, however, instituted late in the course of the infection. At the age of 4 years, this child had a developmental level of 2 years.

Figure 31–9 shows a representative example of the eight patients with milder disease, in six of whom cerebrospinal fluid abnormalities were present. Persistent

lymphocytosis was detected in all, and elevations of cerebrospinal fluid protein levels were distinctly lower (150 to 285 mg/dL) in this group than in the two infants who proved to have severe disease.

Follow-up evaluation in infants who were asymptomatic at birth is discussed under "Follow-up Studies." The data indicate that nearly all children born with subclinical congenital *T. gondii* infection develop adverse sequelae.

How often is congenital infection subclinical? The only prospective data are from studies performed in France, where serologic examination of pregnant women for *T. gondii* infection is obligatory. Couvreur and colleagues reported on a series of 210 infants referred to them because acute acquired infection with *T. gondii* was diagnosed in the mothers before delivery [364]. The series includes all cases of congenital infection prospectively diagnosed from 1972 to 1981. Infants referred because of the presence of clinical signs but who were born to mothers in whom the diagnosis of acute acquired infection had not been previously made during pregnancy were not included (because diagnosis in these cases was retrospective). Among these 210 infants, 2 died during the first year of life; the cause of death in 1 was systemic congenital toxoplasmosis and in the other probably was not related to *T. gondii* infection. Twenty-one infants (10%) had severe congenital toxoplasmosis with CNS involvement. Eye lesions were present in most cases, and systemic disease was present in some. Seventy-one cases (34%) were mild, with normal findings on clinical examination except for the presence of peripheral retinal scarring or isolated intracranial calcifications in an asymptomatic child. Of the 210 infants, 116 (55%) had subclinical infections both at initial examination and at a subsequent examination at the age of 12 months. The frequency of the signs observed is shown in Table 31–13. As pointed out by the investigators, these figures for the respective frequencies of severe, mild, and subclinical cases are biased. Several biases probably decreased the relative frequency of severe congenital infection. The most severe cases with neonatal death were not referred to the investigators, nor probably were those in which congenital toxoplasmosis was so evidently severe that therapy did not appear worthwhile. In addition, an abortion often is performed when acquired infection is diagnosed sufficiently early during pregnancy. This intervention probably decreased the number of infected infants born alive despite early transmission of the parasites, which probably would have resulted in delivery of severely damaged infants (see "Transmission" section). Also, when diagnosis in the mother is made before delivery, treatment with spiramycin has resulted in fewer severely infected offspring and might have decreased the severity of infection in the fetus [78]. In the studies by Couvreur and colleagues [364], the numbers of severe cases were 16 (14%) among 116 infants born to untreated mothers and 3 (4%) in the 79 cases in which the mothers were known to have been treated.

This study [364] also allows for an estimation of the proportion of cases in which infection is really subclinical and of those in which initial signs have in fact not been recognized. Among 116 cases in which infection was considered to be subclinical by the referring physicians, 39 (33%) were discovered to have one or several signs of congenital toxoplasmosis; the most frequent sign was an abnormality on examination of the cerebrospinal fluid.

**TABLE 31–13** Prospective Study of Infants Born to Women Who Acquired *Toxoplasma* Infection During Pregnancy: Signs and Symptoms in 210 Infants with Proven Congenital Infection

| Finding | No. Examined | No. Positive (%) |
|---|---|---|
| Prematurity | 210 | |
| Birth weight <2500 g | | 8 (3.8) |
| Birth weight 2500–3000 g | | 5 (7.1) |
| Dysmaturity (intrauterine growth retardation) | | 13 (6.2) |
| Postmaturity | 108 | 9 (8.3) |
| Icterus | 201 | 20 (10) |
| Hepatosplenomegaly | 210 | 9 (4.2) |
| Thrombocytopenic purpura | 210 | 3 (1.4) |
| Abnormal blood count (anemia, eosinophilia) | 102 | 9 (4.4) |
| Microcephaly | 210 | 11 (5.2) |
| Hydrocephalus | 210 | 8 (3.8) |
| Hypotonia | 210 | 2 (5.7) |
| Convulsions | 210 | 8 (3.8) |
| Psychomotor retardation | 210 | 11 (5.2) |
| Intracranial calcifications on radiography | 210 | 24 (11.4) |
| Abnormal ultrasound examination | 49 | 5 (10) |
| Abnormal computed tomography scan of brain | 13 | 11 (84) |
| Abnormal electroencephalographic result | 191 | 16 (8.3) |
| Abnormal cerebrospinal fluid | 163 | 56 (34.2) |
| Microphthalmia | 210 | 6 (2.8) |
| Strabismus | 210 | 11 (5.2) |
| Chorioretinitis | 210 | |
| Unilateral | | 34 (16.1) |
| Bilateral | | 12 (5.7) |

*Data adapted from Couvreur J, et al. A homogeneous series of 210 cases of congenital toxoplasmosis in 0- to 11-month-old infants detected prospectively. Ann Pediatr (Paris) 31:815–819, 1984.*

In a newborn serologic screening program in Massachusetts, more thorough evaluations of the apparently asymptomatic newborns revealed 20% with eye disease and 20% with neurologic findings [365].

## Prematurity

Prematurity and low Apgar scores are common among newborns with congenital *T. gondii* infection who have clinically apparent disease at birth [96,360,366,367]. In larger series, prematurity has been reported in 25% to more than 50% of the infants. When Lelong and coworkers searched for cases of congenital toxoplasmosis on a single ward of premature infants, they found 7 among 1085 infants (0.6%) [182].

## Twins

In 1965, Glasser and Delta reviewed reports of congenital toxoplasmosis in twins that had appeared in the literature up to that year [61]. Later, Couvreur and colleagues reviewed this subject and added 14 of their own previously

unpublished cases to the literature. Through 1980, we are aware of 35 cases of congenital toxoplasmosis in twins: 11 in monozygotic twins, 13 in dizygotic twins, and 11 whose type is undetermined [61,182,368–372], In 1986, Sibalic and associates reported on a series of 21 pairs of twins with congenital toxoplasmosis in 38 of the infants [373]. *T. gondii* was isolated from four infants. In the remainder, the diagnosis was made by serologic testing alone. Wiswell and coworkers reported congenital toxoplasmosis in triplets [374]. *T. gondii* was demonstrated in the cerebrospinal fluid of each infant; no mention was made of whether the infants were polyzygotic. Each of the three infants had severe disease.

The diagnosis of congenital toxoplasmosis probably would be missed in an asymptomatic twin were it not for specific lesions in the other twin that lead the physician to consider this diagnosis [322,368]. Thus variable clinical patterns have been noted in pairs of twins, and in some sets, one twin died and a subclinical infection existed in the other [322,357,371]. It is doubtful that the diagnosis of congenital toxoplasmosis would have been suspected in the surviving twins without benefit of the results of autopsy in their respective twins [322].

A distinct difference in clinical patterns has been observed between monozygotic and dizygotic twins. In nine pairs of monozygotic twins, the clinical pattern in each twin of a pair most often appears to be similar [61]. For example, chorioretinitis was found in each twin in seven pairs. In addition, with one exception [293], the lesions were either bilateral or unilateral in each twin of each pair considered. Each twin in four sets had hydrocephalus, in four sets cerebral calcification, in four sets convulsions, and in one set mental and motor retardation. In only two sets, in which each infant had hyperbilirubinemia, was there a marked variation from this similarity in clinical pattern in single sets. In each of these sets, one twin died and the other survived [293,322,368]. Among the monozygotic twins, a remarkable predominance of males (eight of nine pairs) was noted, a phenomenon as yet unexplained.

In dizygotic twins, on the other hand, discrepancies in clinical findings within single sets are frequent and marked. In 11 sets of dizygotic twins [368,371,372,375], chorioretinitis was present in 13 of the 22 twins but was observed in both twins of a set in only two instances [368,371,372], and even in these the lesions were not identical. Such discrepancies also were true for virtually all other clinical features in these twins. In many cases, one of the twins had a subclinical infection, whereas in the other it was severe [368,376]. In two sets of twins, one bichorial and biamniotic and the other monochorial and biamniotic, one infant in each set completely escaped infection [368]. An additional report confirms these findings [377].

### Central Nervous System

Other clinical manifestations of CNS destruction are described later under "Mental Retardation," "Down Syndrome," and "Radiologic Abnormalities."

Although in infants with clinical manifestations the signs of congenital toxoplasmosis may vary considerably, widespread destruction of the CNS usually gives rise to the first clinical indications of disease. Among the most common manifestations are internal obstructive hydrocephalus [378], which often is present at birth or appears shortly thereafter and usually is progressive; seizures, which may range from muscular twitching and spasticity to major motor seizures; stiff neck with retraction of the head and, in some cases, opisthotonos; and spinal or bulbar involvement manifested by paralysis of the extremities, difficulty in swallowing, and respiratory distress. Thus the spectrum of neurologic manifestations is protean and may range from a massive acute encephalopathy to a subtle neurologic syndrome. That the infection can involve the spinal cord is highlighted by a case in a 4-week-old girl who had macrocephaly and paralysis of both legs. CT revealed hydrocephalus, and magnetic resonance imaging revealed numerous lesions in the cerebral parenchyma and spinal cord [379]. Eighty-four cases (6.5%) of toxoplasmosis were found among 1282 children younger than 1 year of age who had signs of neurologic disease without obvious underlying causative conditions [363]. (A similar frequency, 4.9%, was reported by Eichenwald [356]). The proportion of cases of congenital *T. gondii* infection was strikingly greater in infants with retinal lesions associated with CNS involvement (62 of 266 cases examined [23%]) than in those who had CNS lesions but no ocular lesions (22 of 1016 cases examined [2.2%]).

It is important to recognize that hydrocephalus due to aqueductal obstruction may be the sole clinical manifestation associated with congenital *T. gondii* infection. Occasionally, the hydrocephalus may be stable, but in most cases, management necessitates a neurosurgical shunt procedure [380]. In a significant number of infants, the prognosis is good, especially after shunt placement; the intelligence quotient (IQ) may be within the normal range. The performance of CT in the months after shunt placement is useful in determining long-term prognosis—which is good if the results of the CT are normal, even in some cases with clinically apparent encephalitis. The prognosis is less promising when there is little expansion of the cortical mantle in the months after ventriculoperitoneal shunt placement. Follow-up CT after shunt placement also is important to exclude subdural collections associated with bleeding from small vessels associated with reduction of pressure when the obstructive hydrocephalus is corrected.

Kaiser has presented a follow-up study of 10 children with hydrocephalus resulting from congenital toxoplasmosis [381]. Hydrocephalus was present at birth in only 3 of the 10 patients and was noted for the first time as late as 11 and 15 months in 2 patients, respectively. All children had progressive hydrocephalus, which required placement of a shunt. In the National Collaborative Chicago-based Congenital Toxoplasmosis Study (NCCCTS), hydrocephalus was present in 45 children. It usually was detected clinically at birth, occasionally prenatally, and after 2 weeks of age in 16 infants. Occasionally, hydrocephalus developed after birth. All children with substantial hydrocephalus, in which there was evidence of aqueductal obstruction and increased intracranial pressure, underwent placement of ventriculoperitoneal shunts.

From 1949 to 1960, Couvreur and Desmonts observed 300 cases of congenital toxoplasmosis [363]. These patients were found by clinical selection. Ocular disorders, particularly chorioretinitis (76%), and neurologic

disturbances (51%) were present in most cases. Twenty-six percent had abnormalities in cranial volume, and 32% had intracranial calcifications.

Toxoplasmosis in children with abnormal cranial volume is uncommon without associated ocular lesions. Of 261 children younger than 2 years of age with hydrocephalus, 16 (6%) had congenital *T. gondii* infection; of 178 children of the same age group with microcephaly, only 3 (1.7%) had congenital *T. gondii* infection. (See also "Microcephaly.")

An interesting case of what appears to have been congenital *T. gondii* infection that manifested as a brain tumor at the approximate age of 1 year was reported by Tognetti and associates [382].

For information on the special problem of congenital toxoplasmosis in infants infected with human immunodeficiency virus (HIV), the reader is referred to "Congenital *Toxoplasma gondii* Infection and Acquired Immunodeficiency Syndrome" later in this section.

## Microcephaly

Baron and coworkers examined the role of *T. gondii* in the pathogenesis of microcephaly and mental retardation [383]. Normal, normocephalic children served as controls, and adequate numbers of microcephalic children ranging in age from 5 months to 5 years were evaluated using the dye test. The data from this study did not reveal significant evidence of an association of *T. gondii* infection and microcephaly. Similar results were obtained by Thalhammer [384] and by Remington [385]. It should be remembered, however, that many microcephalic infants have died before the age of 5 years. Microcephaly in this infection usually reflects severe brain damage, but patients with microcephaly also have developed normally or near-normally.

### Instability of Regulation of Body Temperature

As described in the "Central Nervous System" section under "Pathology," hypothermia may be present and may persist for weeks [6,56,386]. Wide fluctuations in temperature, from hypothermia to hyperthermia, have been reported [293].

## Eye

### Chorioretinitis

Because toxoplasmosis is one of the most common causes of chorioretinitis in the United States and much of the rest of the world, it is important to note that in the past, most workers had considered toxoplasmic chorioretinitis in older children and adults to be the result of a congenital infection rather than a manifestation of acquired toxoplasmosis. From data derived from extensive surveys of cases of uveitis, Perkins concluded that only about 1.5% of patients with toxoplasmic lymphadenopathy have chorioretinitis related to the acquired infection [387]. By contrast, in a study that attempted to determine the percentage of persons having ocular toxoplasmosis in childhood that were due to congenital infection versus infection acquired in childhood, among those with toxoplasmic chorioretinitis in Paris, patients with this disease were divided into groups where diagnosis was definitely congenital, definitely postnatally acquired or uncertain in terms of times of acquisition. In cases where origin of infection could be determined, acquired infections were a more frequent cause of ocular toxoplasmosis than congenital infections. Cases of congenital ocular toxoplasmosis were more severe than acquired cases. Disease that was definitely congenital presented in younger children and was more severe [388].

Attesting to the potential severity of the outcome of congenital ocular toxoplasmosis are results of older studies such as those of Fair [389,390]. In a survey of almost 1000 children in state schools for the blind in the southern United States, Fair concluded that 51 (5%) of the students owed their visual disability to bilateral congenital central chorioretinitis, and of these, a diagnosis of congenital toxoplasmosis was certain or very probable in 40 (4%) [391]. All children showed the nystagmus and squint that always call for further examination. Kazdan and coworkers stated that the most common cause of posterior uveitis in children 15 years of age and younger at the Hospital for Sick Children in Toronto was congenital toxoplasmosis [392].

Congenital bilateral toxoplasmic macular scars, optic atrophy, and congenital cataracts were the major causes (43.5%) of low vision in aretrospective review of a population of 395 consecutive children younger than 14 years of age who attended the Low Vision Service of the State University of Campinas in São Paulo, Brazil, from 1982 to 1992 [393]. Previous studies have revealed similar results [394,395]. It was reported that use of low-magnification (telescopic prescriptions) eyeglasses significantly improved vision in these children and, in 63%, provided both social and personal benefits [393].

To assess the extent of ocular and systemic involvement in adolescent and adult patients with severe congenital toxoplasmosis, Meenken and coworkers [396] from the Netherlands reviewed clinical data, available since birth, in 15 patients whose severe toxoplasmosis was confirmed during the first year of life. The patients were residents of an institute for mentally and visually handicapped children and adults. Nine of them had received postnatal treatment for periods ranging from 2 to 10 months. Mean follow-up was 27 years. Although the diagnosis was made more than 25 years earlier, when more reliable serologic methods were not available, the serodiagnosis seems clear in 13 of the 15. Each of the 15 patients also had the combination of psychomotor retardation, epilepsy, and focal necrotizing retinitis diagnosed as being due to congenital toxoplasmosis. Intracerebral calcifications were present in 12 cases, and in 10 cases, obstructive hydrocephalus had been diagnosed in the first months of life; all received treatment, and all required repeated shunting procedures. In addition to chorioretinitis, the most common abnormal ocular features were optic nerve atrophy (83%), visual acuity of less than 0.1 (85%), strabismus (76%), and microphthalmos (53%). One half exhibited iridic abnormalities, and cataracts developed in approximately 40%. A majority of the cases of iris atrophy were in children aged 5 to 10 years. Of the 8 patients (16 eyes) with iridic atrophy, 12 (75%) had atrophic changes in the globe. In only one case was the chorioretinitis unilateral; it was bilateral in 97% of the remaining cases. In a majority of the cases, severe visual impairment was associated with optic nerve atrophy. The rate of documented recurrences was low (9%) when compared with the recurrence rate in patients

who suffer solely from ocular involvement [397]. Some factors that appeared to account for this low documentation of recurrences were difficulties in examination, including the presence of cataract, extreme microphthalmos, band keratopathy, and lack of patient cooperation. The endocrinologic involvement in these patients is described later in the "Endocrine Disorders" section.

The risk of development of chorioretinitis in congenital cases appears to increase with increasing age during the early years of life. For example, in one case, unilateral (followed by bilateral) chorioretinitis developed between days 90 and 115 in a premature infant who received no treatment for *Toxoplasma* infection, in whom ophthalmoscopic examination was performed every 10 days [398]. By contrast, between 1981 and 1999 in 93 children in the NCCCTS who received treatment, no progression or development of new lesions was observed during the first year of life while treatment was ongoing, but later recurrence was noted in a small number of children [279]. Recurrences were documented in a subset of the children in the NCCCTS who received treatment during their first year of life. All of these children were examined by a single observer at specified intervals. The examinations are performed when they reach 1, 3.5, 5, 7.5, 10, and 15 years of age. The median age for the children who received treatment between 1981 and 1998 was approximately 5 years. The presence of new eye lesions was noted. Data for the children in this cohort in whom eye lesions have developed are presented in Table 31–14, along with various other clinical findings. Another group of children referred to the NCCCTS were designated historical "untreated" patients because they had not received treatment during their first year of life. They usually were referred because quiescent retinal disease was noted (See Table 31–14). Results are similar for over 200 children in the NCCCTS to 2010. New retinal lesions are not noted in the first year, during treatment and rarely occur before 5-7 years of age. The incidence of new lesions is low (10%) for treated children with no signs at birth and 35% for children with severe disease at birth. The most frequent time of recurrences is in adolescence. Children who were diagnosed after the first year of life, who were therefore not treated in the first year of life, had recurrences at the same ages, but had a much higher rate of development of recurrent retinal lesions [883, 884].

In a study by Parissi, among 47 patients with subclinical congenital toxoplasmosis at birth, the overall incidence of retinal lesions was 30% (Table 31–15) [399]. It was less in the first 4 years of life (approximately 23%) than after 5 years of age (40% to 50%). Thus localized ocular phenomena frequently develop as a late manifestation [245,359,361,400]. De Roever-Bonnet and colleagues [245] postulated that late development of eye lesions may be caused by second infections rather than by relapses, although supporting data for this hypothesis are lacking.

The occurrence of consecutive cases of ocular toxoplasmosis has been reported in siblings [401,402]. These cases may have been due to postnatally acquired infection.

Lappalainen and her colleagues observed typical retinal scars of congenital toxoplasmosis in three infants who were seronegative by the age of 1 year. They were born to mothers who had seroconverted during the first trimester [403]. By the age of 5 years, one of these children had seroconverted. Seronegativity in congenital ocular disease also had been observed by Koppe and coworkers in two children who had become seronegative by the ages of 9 and 14 years [190]. Gross and coworkers [404] described the case of a congenitally infected child in whom attempts at diagnosis had failed with relatively insensitive serologic techniques (the CF test) but succeeded with immunoblot and PCR assay; one wonders if IgG antibody would indeed have been demonstrable had serologic testing been performed with more sensitive and specific serologic methods (e.g., the Sabin-Feldman dye test). This case raises the question of how frequently negative results on *T. gondii* serologic studies (and, correspondingly, missed diagnoses) actually occur in children with clinical features considered diagnostic of congenital toxoplasmic retinochoroiditis. In such cases, sera should be tested by multiple methods in a reference laboratory.

### Clinical Findings on External Examination

Microphthalmia, small cornea, posterior cortical cataract, anisometropia, strabismus, and nystagmus may be present. Leukocoria has been reported [279, 405]. Nystagmus may result either from poor fixation related to the chorioretinitis or from involvement of the CNS. A history of "dancing eyes" should always raise the possibility of a bilateral congenital central chorioretinitis—a typical ocular lesion of congenital toxoplasmosis. Convergent or divergent strabismus may be caused by direct involvement of the retina or extraocular muscles or may result from involvement of the brain. The iris and ciliary body may be affected by foci of inflammation, with formation of synechiae. As a result, dilation of the pupils with mydriatics may be difficult.

### Funduscopic Examination Findings

The characteristic lesion of ocular toxoplasmosis is a focal necrotizing retinitis (Fig. 31–10), which may be bilateral [406]. Such lesions in the acute or subacute stage of inflammation appear as yellowish white, cotton-like patches in the fundus. They may be solitary lesions that are about the same size as the optic disk or a little larger. More often, however, they appear in small clusters, among which lesions of various ages can be discerned. The more acute lesions are soft and cotton-like, with indistinct borders; the older lesions are whitish gray, sharply outlined, and spotted by accumulations of choroidal pigment. The inflammatory exudate that is cast off from the surface of the acute lesions often is so dense that clear visualization of the fundus is impossible. In such cases, the most that can be discerned is a whitish mass against the pale orange background of the fundus. The posterior hyaloid membrane often is detached, and precipitates of inflammatory cells—the equivalents of keratic precipitates in the anterior segment of the eye—are seen on the posterior face of the vitreous.

Retinal edema, which affects especially the macular and peripapillary areas, is commonly observed in the subacute phase of inflammation. Edema of the macula is almost

*Data from the U.S. (Chicago) national collaborative treatment trial: patient numbers are those used in all prior publications. Recurrences were documented in a subset of the children in the U.S. (Chicago) National Collaborative Treatment Trial who received treatment during their first year of life. All of these children were examined in Chicago by a single observer at specified intervals. The examinations are when they reach 1, 3.5, 5, 7.5, 10, and 15 years of age. The median age for the children who received treatment is approximately 5 years old. The presence of new eye lesions was noted. Historical patients did not receive treatment in the first year of life and were referred after that time. There were 18 patients in the historical group and 76 in the treatment group.*

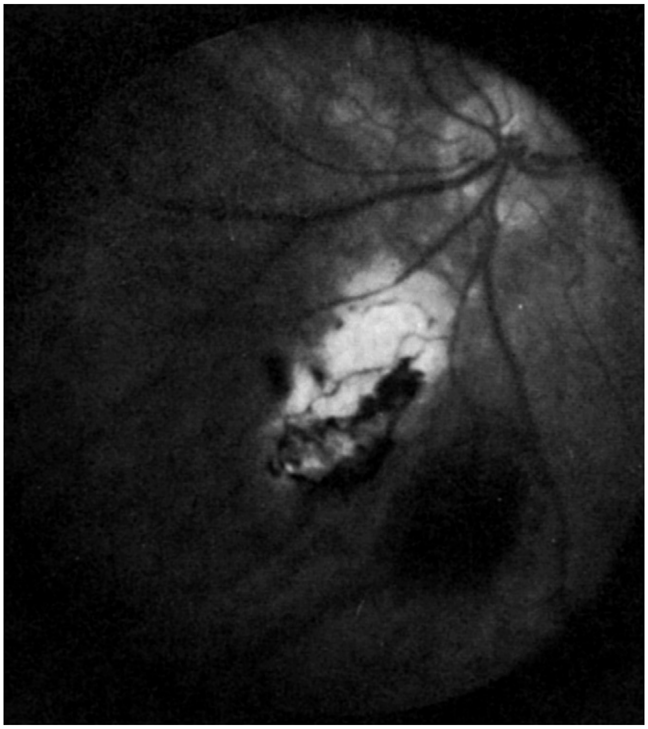

**FIGURE 31–10** Chorioretinitis in congenital toxoplasmosis.

always present when acute inflammatory foci in the retina are situated within the macula. In older children, this edema is the principal cause of blurred vision when other causes, such as a central retinal lesion, involvement of the optic nerve, or extensive clouding of the vitreous, can be excluded. Macular edema usually is temporary, although cystic changes in the fovea sometimes occur as a result of long-standing edema. In this instance, central visual acuity may be permanently impaired despite the absence of central lesions or involvement of the optic nerve. Treatment with an antibody to Veg F can result in resolution of choroidal neovascular membranes [410].

The optic nerve may be affected either primarily, with damage resulting from destruction of the macula and other portions of the retina, or secondarily, with damage resulting from papilledema. Manschot and Daamen and others have described *T. gondii* in the optic nerve itself [290], or optic nerve inflammation [313].

What at first appears to be primary involvement of the optic nerve head, with papilledema and exudation of cells into the overlying vitreous, often turns out to be a juxtapapillary lesion. A retinal lesion contiguous to the head of the optic nerve can produce swelling and inflammation in the nerve, but when the acute lesion subsides, it becomes clear that the optic nerve itself has been spared and that a narrow rim of normal tissue separates the lesion from the nerve head.

Segmental atrophy of the optic nerve, characterized by pallor and loss of substance, especially of the temporal portion of the nerve head, may occur in association with macular lesions. In these cases, the prognosis is for limited vision.

Although a majority of lesions described in the older literature are at or near the posterior pole of the retina, peripheral lesions have been described. In one series of more than 100 children with congenital toxoplasmosis [279], more peripheral lesions were seen. With regard to the relative sizes of the macula and peripheral retina, however, macular lesions were predominant. These have roughly the same morphology as that of the more central lesions, but they tend to be less significant as a cause of central visual loss unless they are accompanied by massive contractures of the overlying vitreous. They can cause subsequent retinal detachment.

The anterior uvea often is the site of intense inflammation, characterized by redness of the external eye, cells and protein in the anterior chamber, large keratic precipitates, posterior synechiae, nodules on the iris, and, occasionally, neovascular formations on the surface of the iris. This reaction may be accompanied by steep rises in intraocular pressure and by formation of cataracts.

Isolated iritis should not be taken as an indication of toxoplasmosis. To be considered as a manifestation of toxoplasmosis, iritis should be preceded or at least accompanied by a posterior lesion. The same can be said of scleritis, which may be observed external to a focus of toxoplasmic chorioretinitis; it has no significance by itself as a sign of toxoplasmosis.

Ophthalmoscopic features of the intraocular lesions of congenital toxoplasmosis in infants are those listed in Table 31–26 (see later discussion) and have been reported [311] to include (1) unilateral or bilateral involvement of the macular region; (2) unilateral or bilateral occurrence of other lesions; (3) involvement of the periphery in one or more quadrants of the retina and choroid; (4) punched-out appearance of large and small lesions in the late phase; (5) occurrence of massive chorioretinal degeneration; (6) extensive connective tissue proliferation and heavy pigmentation, as contrasted with the dissociation of these changes in other chorioretinal lesions; (7) presence of an essentially normal retina and vasculature surrounding the lesions in all stages of the infection; (8) occurrence of associated congenital defects in the eyes; (9) rapid development of sequential optic nerve atrophy; and

(10) frequent clarity of the media in the presence of severe chorioretinitis or chorioretinal scars.

Hogan and coworkers tabulated the data from 22 cases of chorioretinitis in infants 6 months of age or younger with congenital toxoplasmosis (in 81%, the lesions were bilateral) from the literature published through 1949 [407]. A precise determination of prevalence cannot be gleaned from these reports because for many of the infants, the data were incomplete—for example, in some, no description of the fundus was provided, but other features such as microphthalmia were described. Of those infants for whom sufficient information was available, seven had only healed retinal lesions, five had only acute lesions, and four had both acute and healed lesions. Macular involvement was seen in 5, and peripheral retinal involvement in 10; diffuse retinal involvement was present in 3. Twelve infants had microphthalmia, 5 had optic nerve atrophy, 3 had papilledema, 8 had strabismus, 7 had nystagmus, 10 had anterior segment involvement, and 2 had cataracts; in 10, parasites were noted in the retina at autopsy.

Franceschetti and Bamatter reviewed the signs in 243 cases of congenital ocular toxoplasmosis and found the following percentages: bilateral involvement in 66%, unilateral involvement in 34%, microphthalmia in 23%, optic atrophy in 27%, nystagmus in 23%, strabismus in 28%, cataract in 8%, iritis and posterior synechiae in 8%, persistence of pupillary membrane in 4%, and vitreous changes in 11% [408].

The findings of Mets and colleagues [279] in congenitally infected children in the United States who were referred to the National Collaborative Chicago-based Congenital Toxoplasmosis Study (NCCCTS) are shown in Table 31–16. Other important features may be noted. For example, relatively normal visual acuity may occur in the presence of large macular scars either sparing or involving the fovea [279]. Synechiae and pupillary irregularities sometimes are present and reflect an especially severe intraocular inflammatory process. In the NCCCTS, we have noted the following (Noble G and coworkers, unpublished observations): In some patients with severe intraocular inflammation, retinal detachment may occur later in childhood. Intermittent occlusion (patching therapy) of the better-seeing eye may lead to substantial improvement in visual acuity even in the presence of large macular scars. Optical coherence tomography (OCT) may be useful in assessing depth of macular lesions, impact on optic nerve function, and differences over time and thus be of assistance in monitoring recurrences. In the NCCCTS, a small number of mothers had retinal scars, which indicates the importance of retinal examinations for mothers of congenitally infected infants.

A more recent report of eye findings in 173 children in the NCCCTS cohort identified cataracts in 27 eyes of 20 children (11.6%, 95% confidence interval [7.2%, 17.3%]) [409]. In the first year of life, 134 of these 173 children had been treated with pyrimethamine, sulfadiazine, and leucovorin, while the remaining 39 were not treated. Fourteen cataracts were present at birth and 13 developed postnatally. Locations of the cataracts included anterior polar (three eyes), anterior subcapsular (six eyes), nuclear (five eyes), posterior subcapsular (seven eyes), and unknown (six eyes). Thirteen cataracts were partial, nine total, and five with unknown complexity. Twelve cataracts remained stable, 12 progressed, and progression was not known for 3. Five of 27 eyes had cataract surgery, with 2 of these developing glaucoma. Sixteen eyes of 11 patients had retinal detachment and cataracts. All eyes with cataracts had additional ocular lesions. Cataract removal in some cases led to improved visual function.

Choroidal neovascular membranes, which result in accumulation of fluid in the retina and can result in vision threatening bleeding into the retina, have been associated with toxoplasmic chorioretinitis [410].

## Differential Diagnosis of Eye Lesions

**Congenital Anomalies.** The healed foci of toxoplasmic chorioretinitis may resemble a colobomatous defect (Fig. 31–11) [2]. The associated ocular, systemic, and serologic changes make toxoplasmosis the most likely diagnosis. Abnormal retinal morphology has been described in one fetal eye [313], and similar findings have been described in a variety of animal models of the congenital infection. Chromosome analysis was not available for the fetus, however.

**Other Inflammatory Lesions.** The differential diagnosis of eye lesions includes many of the inflammatory

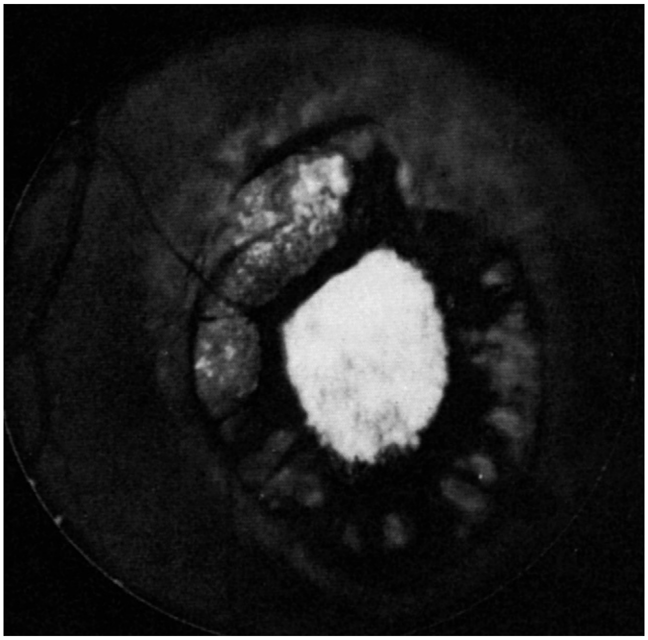

**FIGURE 31–11** Macular scars (pseudocoloboma) of the retina in congenital toxoplasmosis.

lesions described in chapters 16, 23, 26, and 28. The lymphochoriomeningitis virus also can cause similar lesions.

**Birth Injury.** Intraocular hemorrhage may go unrecognized and may cause retinal damage with gliosis and fibrosis, potentially resulting in retinal detachment. The lesion usually is unilateral, associated cerebral damage is absent, and no serologic evidence is present to support a diagnosis of toxoplasmosis. Retinopathy of prematurity may occur in conjunction with toxoplasmic chorioretinitis.

**Circulatory Disturbances.** Congenital aneurysms and telangiectasia of retinal vessels may result in extensive retinal fibrosis, with pigmentation and detachment. The disease usually is unilateral and is not associated with cerebral involvement or other changes.

**Neoplasms.** Retinoblastoma rarely may have an appearance similar to that described for ocular toxoplasmosis. It most often is unilateral and is unassociated with visceral or cerebral damage unless an advanced stage has been reached. Pseudoglioma may be difficult to distinguish from a healed chorioretinitis lesion but usually is single and unilateral. Gliomas may be bilateral, progressing from a small nodule to a large polypoid mass protruding into the vitreous.

### *Mental Retardation*

Numerous studies have attempted to establish a causal relationship between mental retardation and congenital toxoplasmosis. A prospective study on this subject is that of Alford and colleagues [328,411]. When these workers noted that changes in cerebrospinal fluid protein concentration and cell count were common in newborns with subclinical congenital toxoplasmosis, they set out to determine the significance of these changes in relation to later mental development. They compared the intellectual and social development of eight children, aged 2 to 4 years, who were identified at birth as having subclinical congenital toxoplasmosis, with those of eight matched controls. Their results revealed that varying degrees of intellectual impairment may be present in children who are asymptomatic at birth, reflecting the fact that brain damage does occur with subclinical congenital toxoplasmosis. These investigators concluded that although subclinical congenital toxoplasmosis does not necessarily cause overt mental retardation, it may be associated with some degree of intellectual impairment. Further studies along these lines have corroborated these findings (see "Follow-up Studies" later in this section), but until a much larger number of infants are examined over a longer time, these data can be considered only tentative.

The total contribution of congenital toxoplasmosis, including the less severe and clinically inapparent forms at birth, to mental retardation is uncertain. One of the earliest studies from Europe was that of Thalhammer in Vienna, who classified congenital toxoplasmosis into three broad categories: (1) generalized, with hepatomegaly, jaundice, myocarditis, pneumonitis, and similar effects; (2) cerebral, accompanied by at least one of the two characteristic signs, namely, chorioretinitis and intracerebral calcification; and (3) cerebral, accompanied by damage but without these signs [384]. Thalhammer concluded that the first type was rare, the second not common enough to be a problem, and the third a common condition creating serious medical and social problems. He studied 1332 children with congenital cerebral damage that could not be accounted for by postnatal encephalitic illness. The results of this study are summarized in Table 31–17. In children with cerebral defects of all types, the prevalence of *T. gondii* infection was about 17% higher than in normal children. Although the frequency of *T. gondii* infection in this series was not measurably greater in children with microcephaly, hydrocephalus, and cerebral palsy than it was in normal children, it was much greater in those with epilepsy and mental retardation. Thalhammer concluded from these statistics that in about 20% of the cases of mental retardation, the most important cerebral defects were due to congenital toxoplasmosis. Other investigators have similarly concluded from their data that congenital

**TABLE 31–17** Frequency of *Toxoplasma* Infections in 1332 Children (Ages 1–14 Years) with Congenital Cerebral Defects Compared with 600 Normal Children

| Type of Defect | No. Tested | No. Positive* (%) |
|---|---|---|
| Microcephaly | 57 | 2 (3.5) |
| Hydrocephalus | 191 | 17 (8.9) |
| Cerebral palsy | 55 | 5 (9.1) |
| Epilepsy | 344 | 73 (21.2) |
| Mental retardation | 685 | 167 (24.4) |
| Cerebral defects (all types) | 1332 | 264 (19.8) |
| None (normal) | 600 | 20 (3.3) |

**Dye test titers of 1:4 or higher were considered to be positive.*
*Adapted from Thalhammer O. Congenital toxoplasmosis. Lancet 1:23–24, 1962, with permission.*

toxoplasmosis is or may be an important cause of mental retardation [412–415]. Through a series of computations from the data of others, Hume concluded that toxoplasmosis is the cause of impairment in at least 4% of the population composed of the "mentally retarded and [those with] cerebral dysfunction" [416].

Interpretation of many of these studies, and those by workers who found little or no significant difference between mentally retarded and control populations [363,383,417–421], is complicated by the high prevalence of acquired *Toxoplasma* infection among control subjects, which may mask the possible role of congenital toxoplasmosis in mental retardation (and other sequelae of encephalopathy, such as convulsions). For example, if the proportion of cases of mental retardation is small and the prevalence of *T. gondii* antibody titers in the control population is high, it is not possible with presently available diagnostic techniques to distinguish those cases in which *T. gondii* is the cause of mental retardation. Another cause of the variations in reported results is the choice of controls. In many studies, subjects were not properly matched, and any difference or lack of difference found was due solely to differences in populations from which the patients were chosen [420].

Only through large-scale prospective studies of infection with *T. gondii* acquired during the course of pregnancy, compiled by means of long-term observations of the infants, will accurate figures be obtained on the contribution of congenital *T. gondii* infection to mental deficiency (and epilepsy, blindness, and other disorders).

### Down Syndrome

Although numerous investigators have interpreted their data as evidence of an association between toxoplasmosis in the mother and Down syndrome in the offspring [419,422–426], such an association has never been proved satisfactorily [426]. In a study of 71 such children, Thalhammer found a higher-than-normal prevalence of *T. gondii* antibodies [427]. He attributed the higher prevalence to their mental deficiency and suggested that their institutional environment probably favored a higher rate of acquired infection; the prevalence of *T. gondii* antibodies was no different from that in normal controls in the age group birth to 5 years and rose to levels higher than those demonstrated in controls only in the older age groups. Until adequate data to the contrary are furnished, the association between Down syndrome and toxoplasmosis in a newborn must be considered coincidental. Frenkel [428] points out that, in view of the chromosomal aberrations in Down syndrome, it would be necessary to demonstrate that toxoplasmosis is related to the nonhereditary or nondisjunction form of Down syndrome; if this is true, one would have to postulate an influence of *T. gondii* on the ovum, which thus far has not been demonstrated [423]. Much of the literature on this subject, and that on the relationship of toxoplasmosis to other entities in the newborn, is purely speculative.

### Endocrine Disorders

The endocrine disorders that have been associated with congenital toxoplasmosis are nonspecific because they reflect the severity of the infection in those areas of the brain that are related to endocrine function. Two cases in which congenital toxoplasmosis and congenital myxedema occurred simultaneously have been reported [429,430]. Because each of these conditions is relatively uncommon, their concurrent appearance suggests more than mere coincidence. *T. gondii* has been demonstrated in histologic sections of the pituitary and thyroid glands of infants dying of toxoplasmosis, and it may be that such involvement contributed to or resulted in myxedema in these patients. Silver and Dixon described persistent hypernatremia in a congenitally infected infant who had evidence of vasopressin-sensitive diabetes insipidus without polyuria or polydipsia [386]. An associated finding was a marked eosinophilia in blood and bone marrow. A similar case was described by Margit and Istvan [431]. Diabetes insipidus has occurred in the perinatal period or developed later in childhood [431,432]. This disorder in such cases probably is secondary to pituitary-hypothalamic *T. gondii* infection. It has occurred in infants and children with severe brain damage and hydrocephalus, and in children who have only intracerebral calcifications [433–435].

Bruhl and colleagues reported sexual precocity in association with congenital toxoplasmosis in a male infant who, at the age of 2 years, showed rapid growth of the external genitalia and appearance of pubic hair, along with generalized convulsions, microcephaly, severe mental retardation, bilateral microphthalmia, and blindness (deafness was suspected because the child did not respond to noises) [436]. After 9 years of hospitalization, he died at the age of 13.5 years. The early onset of growth of the penis and testes and the development of pubic hair, and testicular biopsy and hormone assays, established the diagnosis of true precocity in this case. A cause-and-effect relationship between toxoplasmosis and precocious puberty could not be proved, but the presence of two rare disorders in the same patient suggested such a relationship. Also, a variety of lesions involving the hypothalamus have been associated with precocious puberty, and the third ventricle was dilated and the hypothalamus was distorted in the patient just described. The anterior pituitary appeared normal at autopsy—a prerequisite to development of precocious puberty in patients with lesions in or near the hypothalamus. Partial anterior hypopituitarism was observed in the infant reported by Coppola and coworkers [437]. Massa and colleagues described three children with growth hormone deficiency, two of whom were gonadotropin deficient and one of whom had precocious puberty, in addition to central diabetes insipidus [429].

In the study performed by Meenken and associates [396] (described previously in the "Chorioretinitis" section), overt endocrinologic disease was diagnosed in 5 of 15 patients with severe congenital toxoplasmosis, all of whom had serious eye disease due to the infection. Panhypopituitarism was observed in two, gonadal failure with dwarfism in one, precocious puberty with dwarfism and thyroid deficiency in one, and diabetes mellitus and thyroid deficiency in one. The investigators found that the major manifestations of the endocrine disease in these patients occurred at the mean age of 12 years (range, 9 to 16 years) and were associated with obstructive hydrocephalus and dilated third ventricle in each case.

## Nephrotic Syndrome

In infants with congenital toxoplasmosis, generalized edema and ascites may reflect the presence of the nephrotic syndrome [324,438,439]. Protein and casts have been reported in the urine in such cases, as have hypoproteinemia, hypoalbuminemia, and hypercholesterolemia. In one case, there was a marked decrease in the serum IgG level, but IgM and IgA levels were normal [439]. Hypogammaglobulinemia has been reported to be associated with congenital toxoplasmosis in the absence of nephrosis [440].

## Liver

Kove and coworkers described the pattern of serum transaminase activity in a newborn with cytomegalic inclusion disease and in another with congenital toxoplasmosis [441]. Jaundice developed in both. The patterns were unique and unlike those observed in infants with other causes of neonatal jaundice. The investigators pointed out that more studies are necessary to determine if serial measurements of serum transaminase will actually be a useful tool in the diagnosis of congenital toxoplasmosis and cytomegalic inclusion disease.

Jaundice, which occurs frequently, may reflect liver damage or hemolysis, or both. Among 225 infants with neonatal icterus studied by Couvreur and Desmonts, 5 (2.2%) were found to have congenital toxoplasmosis [363]. The conjugated hyperbilirubinemia and jaundice seen in infants with untreated congenital toxoplasmosis may persist for months [304]. In infants who receive treatment, hyperbilirubinemia and jaundice usually resolve in a few weeks.

## Skin

Like almost all other signs of the infection, those referable to the skin are varied and nonspecific [442,443]. Thrombocytopenia may be associated with petechiae, ecchymoses, or even gross hemorrhages into the skin. Zuelzer described a fine punctate rash over the entire body of a 3-day-old infant [293]. Miller and colleagues noted albinism in one of the infants they studied but did not consider this to be caused by toxoplasmosis [322]. Wolf and associates noted a diffuse maculopapular rash in two infants with jaundice, beginning on the sixth day in one and on the ninth day in the other [304]. Reiss and Verron described a premature infant with a lenticular, deep blue-red, sharply defined macular rash over the entire body, including the palms and soles [444]. Diffuse blue papules [445] and "blueberry muffin" rash [446] (Fig. 31–12) have been observed in infants with congenital toxoplasmosis and those with congenital Rubella and other infections (see Chapter 1). Korovitsky and coworkers, in a discussion of skin lesions in toxoplasmosis, mentioned an exfoliative dermatitis in cases of congenital toxoplasmosis [447], but according to Justus, a cause-and-effect relationship between these two conditions was not shown in the infant he described [445]. In 1968, Justus reported complete calcification of the skin, except for the palms and soles, in a premature infant who died 10 minutes after birth [445]. The mother had experienced tetany during delivery and required supplemental calcium

**FIGURE 31–12** "Blueberry muffin" rash in an infant with congenital toxoplasmosis. *(From Mehta V, Balachandran C, Lonikar V. Blueberry muffin baby: a pictorial differential diagnosis. Dermatol Online J 14(2):8, 2008.)*

thereafter. Thus the calcifications may not have been due solely, or even in part, to congenital toxoplasmosis in the infant but rather may have been the result of a metabolic defect in calcium metabolism in the mother.

## Malformations

The possibility that *T. gondii* can cause fetal malformations has been the subject of much conjecture. Thalhammer, commenting on the accumulated data on this subject, stated that he did not believe that *T. gondii* causes malformations [427]. He found 4 instances of malformations among 326 cases of congenital toxoplasmosis (1.2%), and this was less than the average incidence of malformations in his geographic area. Of 144 children with malformations, only 2 had *T. gondii* antibodies.

By contrast, workers in Germany [73,448–450], Greece [451], the former Czechoslovakia [452], and the former Soviet Union [453] interpret their data as proof that *T. gondii* causes fetal malformations. Most of these studies were performed in an uncontrolled and uncritical manner. For example, in the United States, Erdelyi suggested that some cases of palatal cleft malformations may be due to congenital toxoplasmosis [454]; a similar conclusion was reached by Jírovec and coworkers in Prague [454, 455]. The evidence in the study reported by Erdelyi consisted of dye test data, and in the study from Jírovec's group, skin test data drawn from investigations of mothers of children with cleft palate and harelip defects; the prevalence of positive results on skin testing in mothers of such children was found to be higher than that in controls from the general population. Carefully chosen controls should be a necessary feature of all such studies; results obtained from the general population are not applicable or valid.

Although involvement of the placenta by infection early in pregnancy might cause damage without direct infection of the developing embryo, the available data are insufficient either to support or to reject the hypothesis that *T. gondii* can cause fetal malformations. This problem is easily approached with existing epidemiologic methods and awaits careful controlled study.

## Radiologic Abnormalities

### Brain

Hydrocephalus characteristically is due to periaqueductal involvement. Obstruction of the aqueduct of Sylvius leads to enlargement of the third and lateral ventricles (Fig. 31–13, *A*). Obstruction of the foramen of Monro can lead to unilateral hydrocephalus (Fig. 31–14) (see also Fig. 31–13, *B*) [433]. Dramatic resolution and brain cortical expansion and growth can occur in conjunction with ventriculoperitoneal shunt placement and anti-*T. gondii* therapy (see Figs. 31–12, *C* and *D*). Calcifications may be single or multiple (Fig. 31–15; see also Fig. 31–13, *E* to *H*) and, surprisingly, in some cases have resolved with anti-*Toxoplasma* therapy during the first year of life (see Figs. 31–13, *E*) [456]. Contrast-enhancing lesions have been detected, indicating active encephalitis (see Fig. 31–13, *G*) [433]. Massive hydrocephalus, as

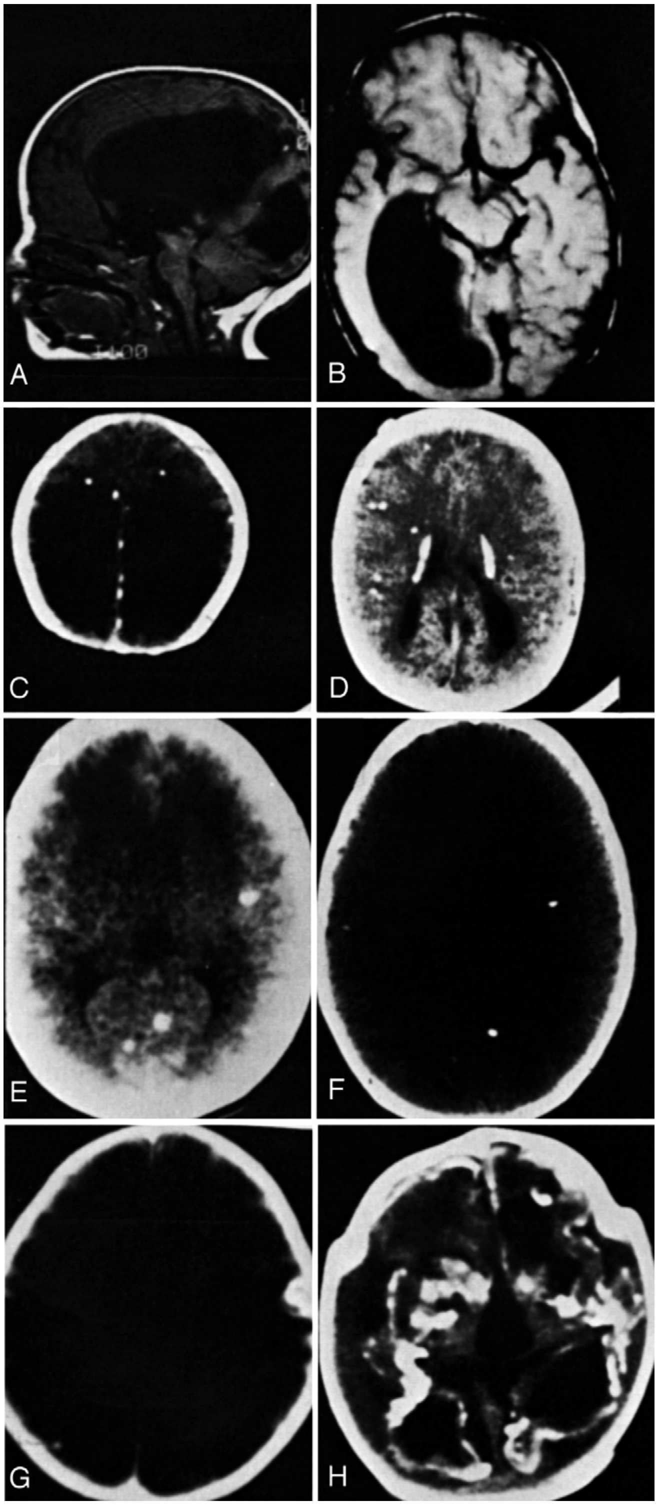

**FIGURE 31–13** Neuroradiographic findings in congenital toxoplasmosis and improvements following treatment. **A**, Magnetic resonance imaging (MRI) study of the brain demonstrating obstruction of the aqueduct of Sylvius and consequent dilation of the third and lateral ventricles. **B**, MRI study of the brain demonstrating unilateral hydrocephalus. **C** and **D**, Brain computed tomography (CT) scans in the early newborn period **(C)** and of the same child at 1 year of age **(D)** following shunt placement and antimicrobial therapy. The child was developmentally and neurologically normal at 1 year of age. **E** and **F**, Brain CT scans from another child in the early newborn period **(E)** and at 1 year of age **(F)** following antimicrobial therapy. The resolution or diminution of calcifications is noteworthy and has occurred in a substantial number (but not all) of children who received appropriate treatment in the Chicago study. This child also is developmentally and neurologically normal. **G**, Brain CT scan that demonstrates a ring-enhancing lesion and calcifications. **H**, Brain CT scan showing extremely extensive intracerebral calcifications and hydrocephalus. **C** to **E**, Diminution and/or resolution of large areas of calcification are seen in these representative cranial CT scans from another infant. The scans were obtained at birth, February 1987 **(C)**, and at follow-up in May 1988 **(D)** and July 1991 **(E)**. continued *(**B, E, F, G** from McAuley J, et al. Early and longitudinal evaluations of treated infants and children and untreated historical patients with congenital toxoplasmosis: the Chicago collaborative treatment trial. Clin Infect Dis 18:38–72, 1994; Remington JS, et al. Toxoplasmosis.* In *Remington JS, Klein JO [eds]. Infectious Diseases of the Fetus and Newborn Infant, 5th ed. Philadelphia, WB Saunders, 2000.)*

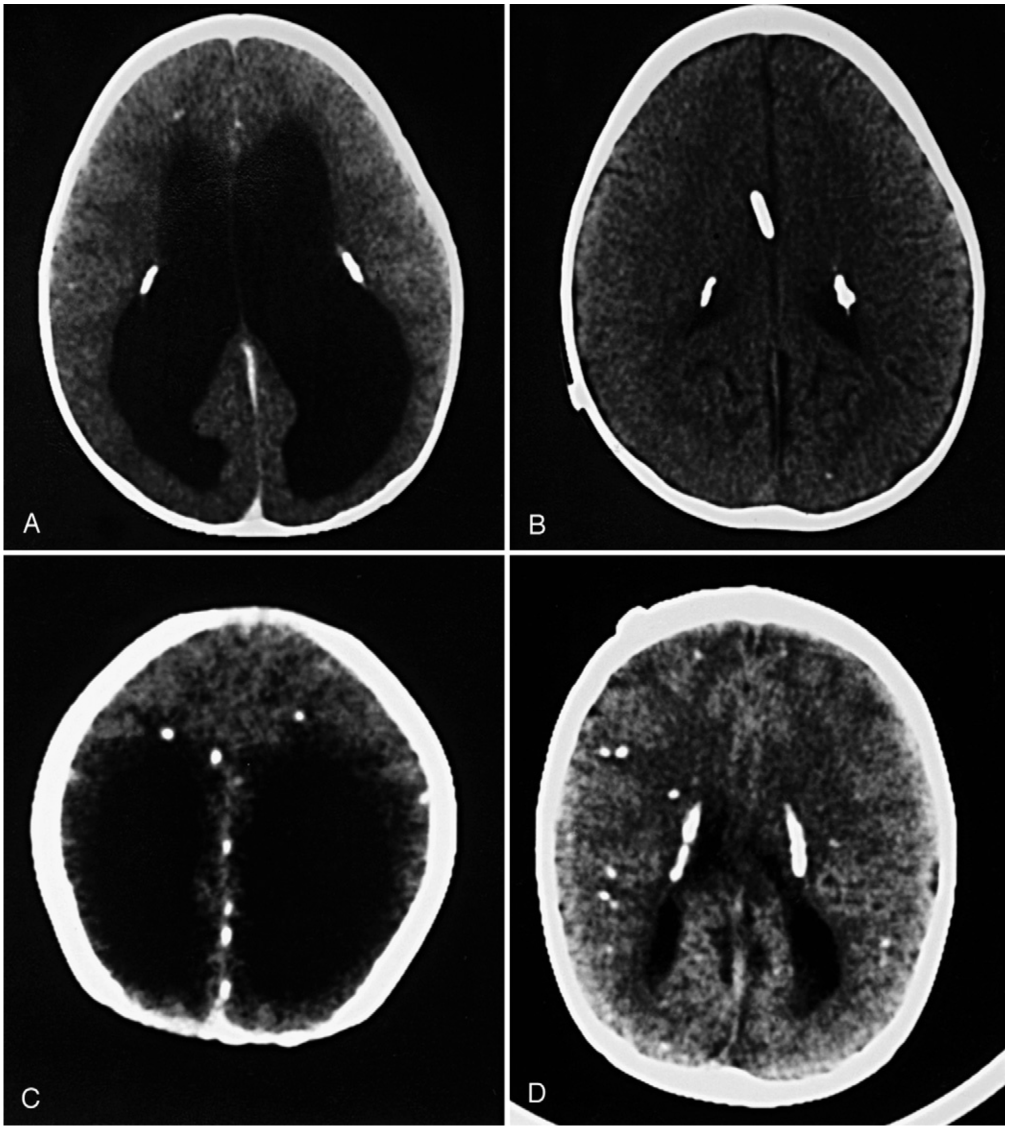

**FIGURE 31–14** Cranial computed tomography (CT) scans of two infants, one represented in **A** and **B** and the other in **C** and **D**, before (A and C) and after (B and D) placement of ventriculoperitoneal shunts. CT scans and the subsequent normal development of such children indicate that it is not possible to predict ultimate cognitive outcome from the initial appearance of the CT scan. *(From Boyer KM, McLeod RL.* Toxoplasma gondii *[toxoplasmosis].* In *Long SS, Prober CG, Pickering LK [eds]. documented by ultrasound examination, has been noted to develop in fetuses and newborns within a period as brief as 1 week and resolved in association with anti-*Toxoplasma* treatment in one fetus (Fig. 31–16) [457].

Radiologic signs in newborns exposed to primary *T. gondii* infection in utero were described by Virkola and colleagues [456]. The study included 42 mothers—37 were delivered of live-born infants and 5 experienced spontaneous abortions—with follow-up evaluation. The findings on brain ultrasonography associated with infection included calcifications, cysts, and the "candlestick sign"; those on abdominal ultrasonography were enlarged spleen and ascites. In some instances, these changes were associated with abnormalities in the newborn period.

Puri and coworkers described a 2-week-old infant with hydrocephalus [458]. A brain scan with $^{99m}$Tc-pertechnetate showed an area of increased uptake in the left temporoparietal region. A four-vessel angiogram showed large ventricles with a mass lesion in the left hemisphere pushing midline structures to the right. Findings on electroencephalography were abnormal, with sharp θ activity in the left parietotemporal area. A bubble ventriculogram showed obstruction of the left foramen of Monro. Because of the rapid deterioration of the patient's condition, a craniotomy was performed; it revealed a large granular infiltrating tumor in the left temporal region. Numerous *T. gondii* organisms were seen in the operative specimen of the brain. A similar cerebral mass lesion was described by Hervei and Simon in a case of congenital toxoplasmosis [459] and by Bobowski and Reed in a case of acquired toxoplasmosis [460]. Hervas and colleagues described a newborn with congenital toxoplasmosis whose cranial CT scan with contrast enhancement demonstrated calcifications and multiple ring-enhancing lesions not dissimilar to those seen in adult

patients with AIDS, with multiple brain abscesses related to *T. gondii* [305]. McAuley and coworkers [433] also described enhancement around a lesion that resolved with antimicrobial treatment.

A CT scan, which allows for neuroanatomic localization of intracranial calcifications, delineation of ventricular size, and recognition of cortical atrophy, has proved to be valuable in evaluation of congenital toxoplasmosis [461–463]. Diebler and associates published results of CT scans in 32 cases of congenital toxoplasmosis [462]. They reported a clear relationship between the lesions observed on these scans, neurologic signs, and date of maternal infection. The destructive lesions were porencephalic cysts that when multiple may constitute multicystic encephalomalacia or even hydranencephaly. Dense and large calcifications were seen in the basal ganglia in seven cases, with or without periventricular calcifications. Hydrocephalus was always secondary to aqueductal stenosis. In one case, ocular calcification was noted. In a retrospective study of cases in which pachygyria-like changes were observed on CT or magnetic resonance imaging, a single case of congenital toxoplasmosis was noted [464]. Ultrasonography also has been suggested as useful for diagnosis of congenital toxoplasmosis. CT scan of the brain detects calcifications not seen with ultrasonography of the brain [465,466]. Brief MRI (an axial single shot T2 MRI requiring 30-45 seconds) may be useful for following ventricular size when a child has had a VP shunt or otherwise requires follow-up of ventricular size. It can be performed with no sedation or contrast, lowering risks and complications (R. McLeod, unpublished observations).

### Intracranial Calcification

With rare exceptions [319], the deposits of calcium noticed in congenital toxoplasmosis have been limited to the intracranial structures. The deposits are scattered throughout the brain and in some studies have been reported to have no characteristic distribution. In other studies, many children were observed to have prominent basal ganglia and periventricular califications [467–470]. Masherpa and Valentino described two types of calcifications: (1) multiple, dense round deposits 1 to 3 mm in diameter scattered in the white matter and, more frequently, in the periventricular areas of the occipitoparietal and temporal regions and (2) curvilinear streaks in the basal ganglia, mostly in the head of the caudate nucleus

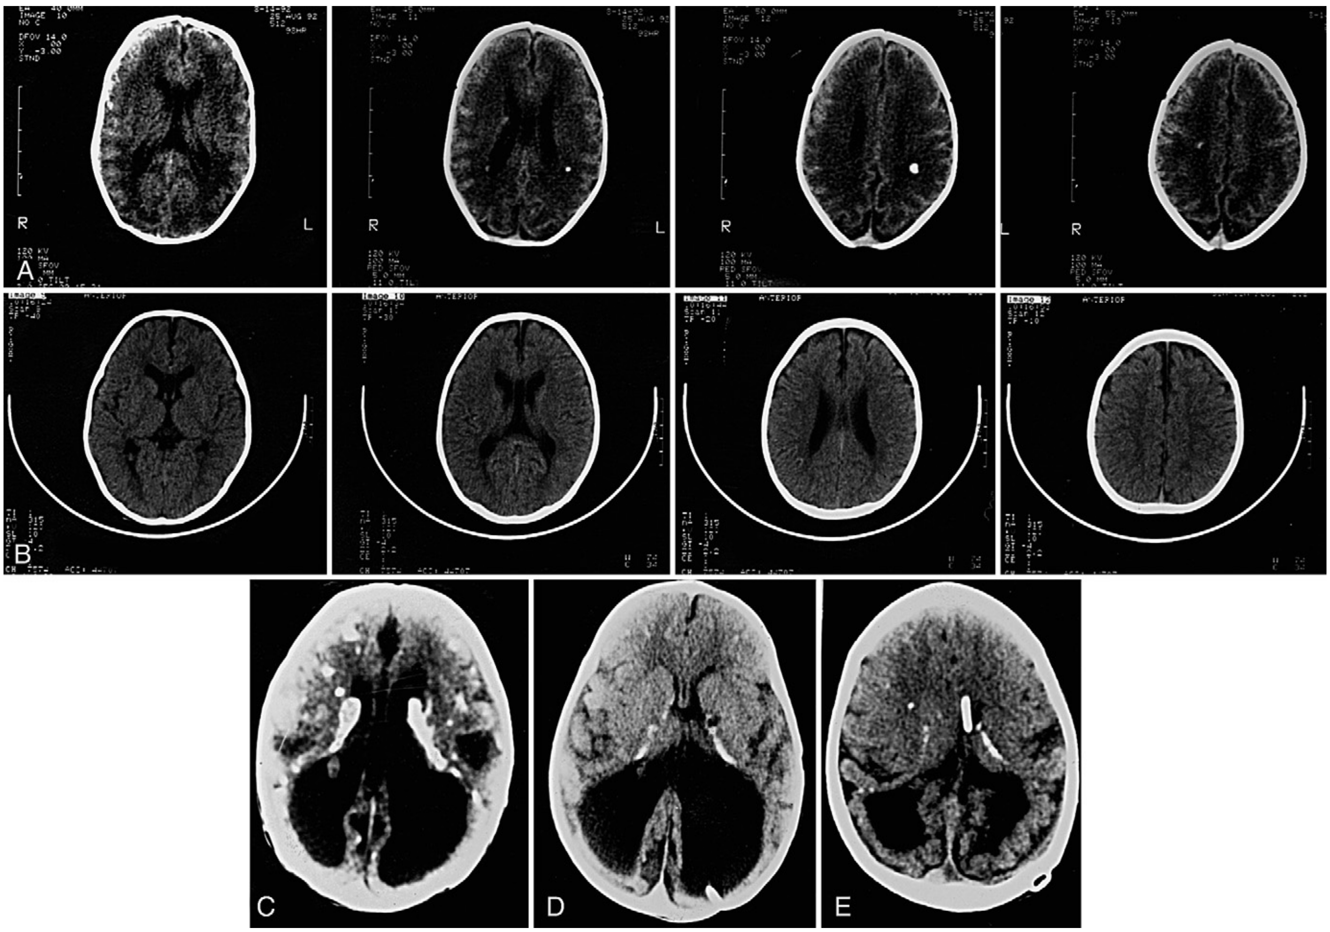

**FIGURE 31–15** Additional examples of cranial computed tomography (CT) scans that demonstrate resolution of calcifications in children following treatment for congenital toxoplasmosis. **A** and **B**, CT scans in an infant obtained at birth, August 1992 (A), and in August 1993 (B). **C** to **E**, Diminution and/or resolution of large areas of calcification are seen in these representative cranial CT scans from another infant. The scans were obtained at birth, February 1987 (C), and at follow-up in May 1988 (D) and July 1991 (E).

*Continued*

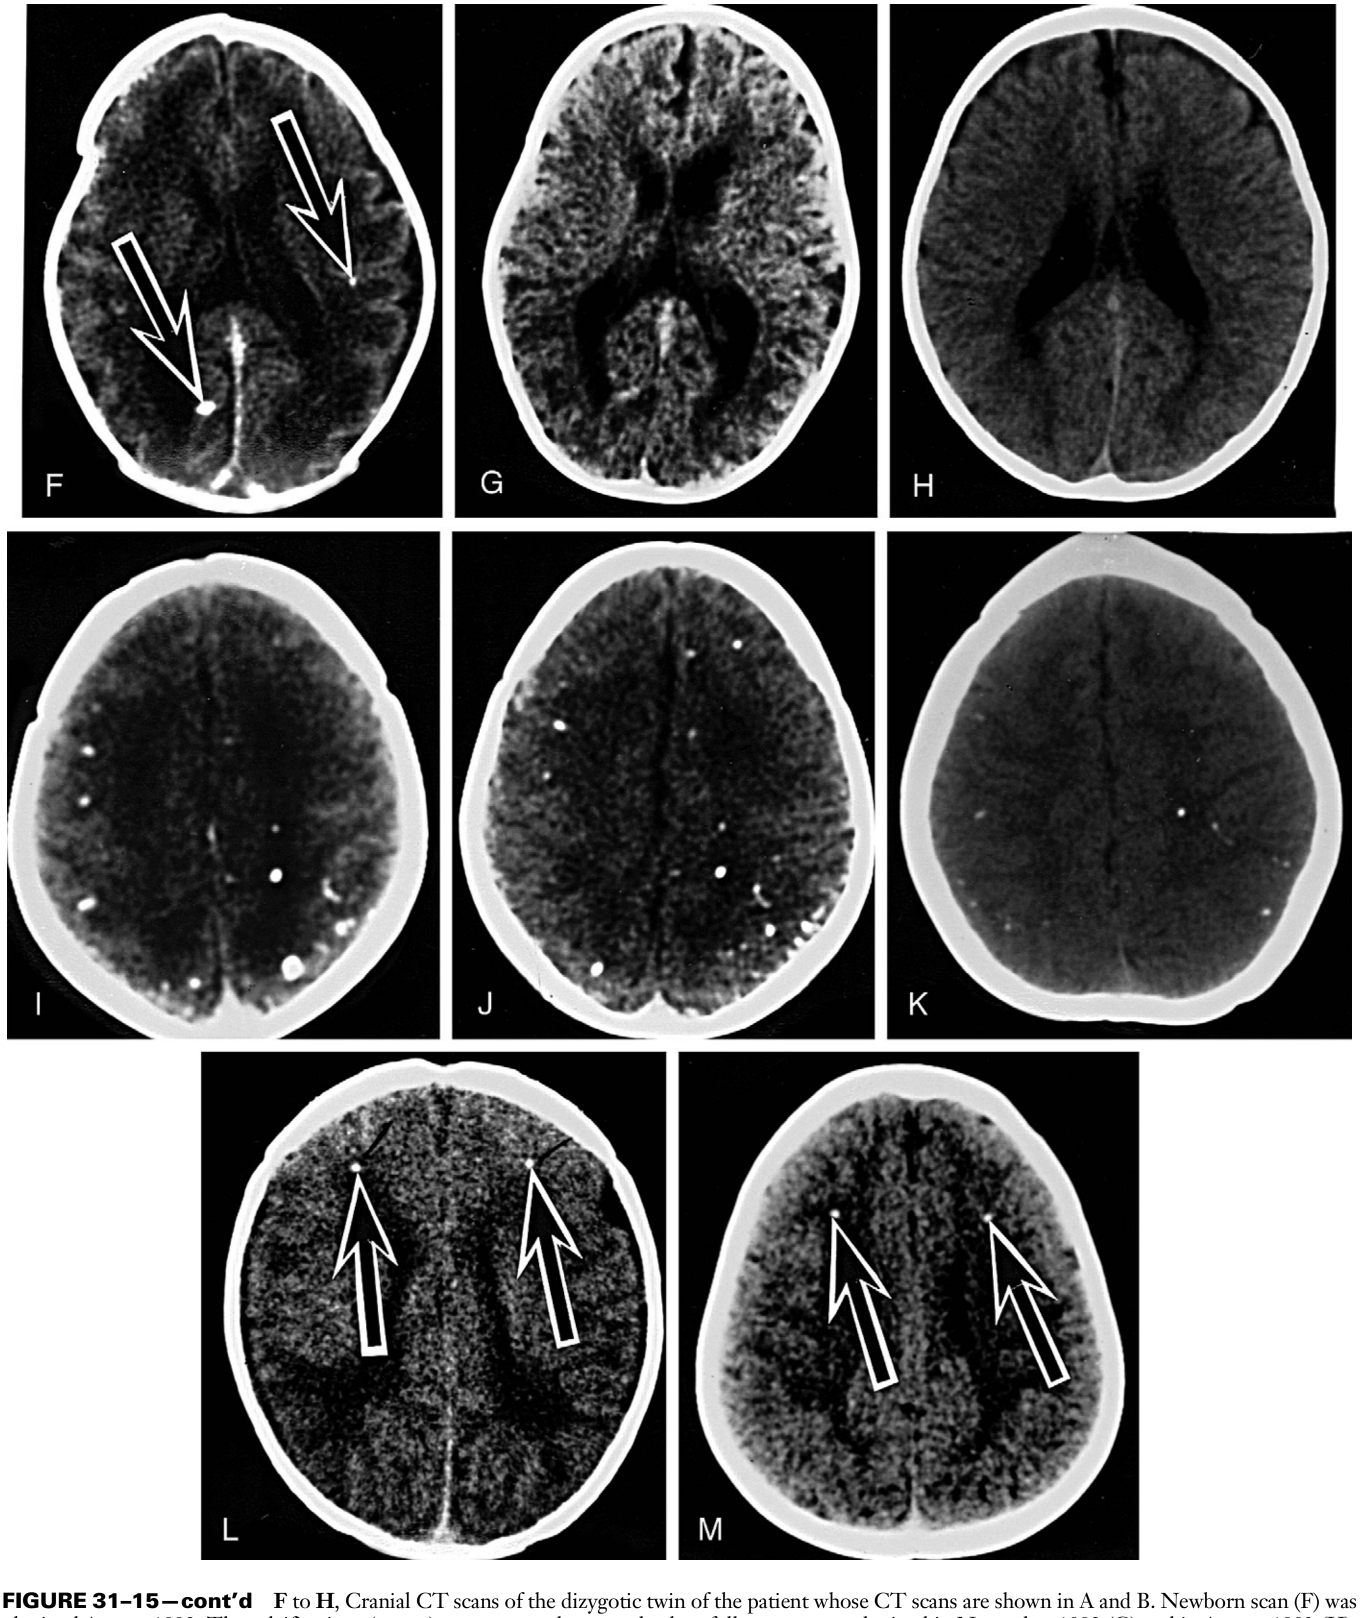

**FIGURE 31–15—cont'd** **F** to **H**, Cranial CT scans of the dizygotic twin of the patient whose CT scans are shown in A and B. Newborn scan (F) was obtained August 1992. The calcifications (*arrows*) were seen to have resolved on follow-up scans obtained in November 1992 (G) and in August 1993 (H). Note: The patient whose scans are shown in A and B was randomized to receive initial higher dose therapy (6 months of 1 mg/kg/day of pyrimethamine), and the patient whose scans are shown in F to H was randomized to receive initial lower dose therapy (2 months of 1 mg/kg/day of pyrimethamine). Both infants completed 1 year of treatment with pyrimethamine 1 mg/kg each Monday, Wednesday, and Friday and sulfadiazine. Calcifications were seen to have resolved completely in cranial CT scans of both twins. **I** to **K**, Cranial CT scans obtained for another infant in the newborn period, January 1993 (I), and at follow-up in February 1993 (J) and January 1994 (K) demonstrate diminution and/or resolution of calcifications. This child has developed normally. **L** and **M,** Cranial CT scans obtained in the newborn period, May 1991 (L) and in August 1992 (M) in a different, noncompliant child who underwent treatment in our study for only 1 month. Arrows mark calcifications that remained the same size. *(From Patel DV, et al. Resolution of intracranial calcification in infants with treated congenital toxoplasmosis. Radiology 199:433–440, 1996, with minor modifications and permission.)*

[471]. Some workers consider that evidence of both nodular calcifications and linear calcifications is pathognomonic of toxoplasmosis (Figs. 31–17 and 31–18).

Although in cytomegalic inclusion disease the calcifications are located chiefly subependymally and are bilaterally symmetrical, mostly in the walls of the dilated ventricles [469,470], these locations also are noted in congenital toxoplasmosis. The largest series of cases of cerebral calcification related to congenital toxoplasmosis are those of Dyke and colleagues [472] and of Mussbichler [473]. The latter reviewed material from 32 clinically well-documented cases. Approximately one third of the patients were 3 months of age or younger, and 80% were younger than 2 years of age. Mussbichler's findings—some original and others confirming the findings of others—revealed that calcifications in the caudate nucleus, choroid plexuses, meninges, and subependyma are characteristic in toxoplasmosis, although some of these locations also have been described in cytomegalic inclusion disease. Because calcifications were present in

multiple areas of the brain in the cases he reviewed, he concluded that calcifications found in the choroid plexuses alone should not be regarded as evidence of toxoplasmosis. Mussbichler found calcifications in the meninges that had not previously been described and attributed his ability to locate them to the use of appropriate projections that delineated them clearly. For those children who did not receive treatment, calcifications in the meninges and caudate nucleus were signs of a poor prognosis; they were found only in the youngest children, who died early. Conversely, disseminated nodular calcifications do not necessarily suggest a poor prognosis and have been discovered fortuitously in "normal" infants who were studied at approximately 1 year of age; in these children, a diagnosis of congenital toxoplasmosis had been made through a systematic survey. The increase in size and number of calcific lesions during a period of months or years in some cases suggests that the process of healing (and perhaps also of destruction) may occur long after the onset of the infection. Calcifications can diminish in size or resolve with treatment [456].

### Osseous Changes

In 1974, Milgram described the radiographic signs present in an infant who died 17 days after birth with a severe clinical form of congenital toxoplasmosis [292]. Roentgenograms of several ribs and vertebrae and one femur revealed bands of metaphyseal lucency and irregularity of the line of provisional calcification at the epiphyseal plates. Periosteal reaction was not present. (Syphilis also may cause this same finding.)

### Liver

Although it has been stated that calcifications do not occur outside the CNS in infants with congenital toxoplasmosis, Caldera and colleagues described cases of three infants with calcifications in the liver [319]. The calcifications were evident both radiologically and in the liver at autopsy.

### Other Signs and Symptoms

**Erythroblastosis and Hydrops Fetalis.** Congenital toxoplasmosis may be confused with erythroblastosis related to isosensitization [299,423,474–479]. The peripheral blood picture and clinical course may be identical to those observed in other forms of erythroblastosis. This similarity is exemplified by cases such as those reported by Callahan and colleagues [288] and by Beckett and Flynn [62]. A negative Coombs test result is helpful in distinguishing erythroblastosis caused by congenital infection from that caused by blood group factor sensitization. In one case, fetal hydrops due to congenital toxoplasmosis resolved in association with treatment of toxoplasma infection with pyrimethamine, sulfadiazine with leucovorin between the 27th and 37th weeks of gestation (R. McLeod and colleagues, unpublished observation).

**Cardiovascular Signs.** Severe toxoplasmic myocarditis may be manifested clinically as edema [288].

**Gastrointestinal Signs.** In some cases, the first sign of the disease appears to be vomiting or diarrhea [288]. Feeding problems also are common.

**Respiratory Difficulty.** Respiratory difficulty [6,288], often with cyanosis, may be due to an interstitial toxoplasmic pneumonitis, to viral or bacterial suprainfection, or to CNS lesions affecting the respiratory control centers of the brain.

**Deafness.** From the follow-up studies of Eichenwald [356] and others [480], ample clinical and histologic [56,288,314,368,481] data are available to show that congenital infection with *T. gondii* can lead to deafness. The well-documented cases of profound hearing loss have been almost totally confined to infants with severe clinical disease, but in the series of children with subclinical infection at birth reported by Wilson and associates [480], 17% had significant hearing loss. In some instances, serologic and skin test surveys among deaf patients have suggested a cause-and-effect relationship [482], whereas in others, no such relationship has been found [483]. An association between epilepsy, cerebral palsy, and nerve deafness and the presence of antibodies to *T. gondii* in sera of Israeli children was noted (relative risk 2.5, $P = .03$; nerve deafness relative risk 7.1, $P = .01$) [484]. Such studies frequently are open to criticism, owing to the choice of controls. Thus no satisfactory data are available to support the contention that congenital toxoplasmosis may be a frequent cause of deafness [485]. In the NCCCTS, as of June 2010, no treated child with sensorineural hearing loss was identified (Table 31–18) [486]. One child with brainstem lesions involving the auditory nucleus had auditory perceptual difficulties.

**Ascites.** Vanhaesebrouck and coworkers described a preterm congenitally infected infant with isolated transudative ascites caused by *T. gondii* [487]. Neonatal [488] and fetal [77,489,490] ascites due to congenital toxoplasmosis have been reported.

## Follow-up Studies

Adequate follow-up studies (see also the previous "Eye" section) to gain information on the natural course of congenital toxoplasmosis are lacking in most series of reported cases. In the vast majority, the original diagnosis was made in a retrospective manner, in most cases because of the presence of clinical signs of the infection. Most accumulated data, therefore, are from infants and older children with the most atypical form of congenital toxoplasmosis, that is, clinically apparent disease in the newborn period. It is in those infants who are actually in the majority—those who were asymptomatic at birth—that there is the greatest need for follow-up studies, such as those performed by Alford and colleagues [328,411], described previously. (See also the published studies by Hedenström and colleagues [491,492]). Findings on follow-up evaluation of the infants who were asymptomatic at birth in the Paris study are difficult to interpret because most were given treatment in the newborn period. In some, however, recognition of the first clinical finding

(usually chorioretinitis) was delayed until several weeks or months after birth, thereby illustrating an often reported observation in congenital toxoplasmosis: the normal appearance of a child for some months before overt disease is recognized [61,359,380,493].

Follow-up studies of those patients described by Eichenwald have already been mentioned. Two patients reported by Wolf and coworkers in 1942 [304] were still alive in 1959 and were being cared for in mental institutions [494]. One of them, first seen at the age of 3 years and 9 months, was about 22 years old at the time of the second report. She was mentally and physically retarded and oblivious to her environment, drooled constantly, was resistant to care and feeding, and was losing weight. She continued to have petit mal and grand mal seizures. Old chorioretinal scars were still present. The second patient was 2 years old when the diagnosis was made and about 18 years of age at the time of the last report. His IQ was only 40. He was said to have a pleasant personality and could engage in some project activities. Vision was 20/100 in one eye and 20/70 in the other.

Feldman and Miller analyzed 187 patients with congenital toxoplasmosis. Among 176 of these patients, 119 were 4 years of age or younger, 38 were 5 to 9 years of age, and 19 were 10 to 19 years of age [96]. Thirty-six had been delivered prematurely; 20% of the premature infants and 7% of those born at term died. Residual damage varied in degree, but most of the patients exhibited chorioretinitis, mental retardation, and abnormalities of head size. In this series, reported frequencies of abnormalities were as follows: intracerebral calcification, 59%; psychomotor retardation, 45%; seizures, 39%; chorioretinitis, 94%; microphthalmia, 36%; hydrocephalus, 22%; and microcephaly, 21% [357].

Puissan and coworkers observed the late onset of convulsions in an 8-year-old girl with congenital toxoplasmosis [495]. Of interest in this case was the demonstration of what appears to have been local production of *T. gondii* antibody in the cerebrospinal fluid when the convulsions began.

In the first report of the prospective study by Koppe and colleagues, follow-up data were obtained for 7 years for 12 congenitally infected children [360]. Four children had clinical signs (ocular only), and one was clinically normal but *T. gondii* had been isolated from the placenta and cerebrospinal fluid; these five were given pyrimethamine and sulfadiazine. No signs of cerebral damage or intracranial calcifications developed in any of the children, and all were said to be "mentally normal" at the age of 7 years [360]. Their development was judged by their performance in school, which was stated to be normal. In fact, in a later report, chorioretinal scars were present in 82% of these children [245], and because they were still younger than 15 years of age when last reported, they remained at risk for the development of additional sequelae. (See the "Amsterdam Study" section later for the final report.)

### *Congenital Toxoplasma Infection and Acquired Immunodeficiency Syndrome*

Congenital transmission of *T. gondii* from pregnant women coinfected with *T. gondii* and HIV has been recognized as a unique problem [496–503] but fortunately a relatively uncommon one [504–510]. Documentation of previous infection before conception and the absence of demonstrable IgM antibodies to *T. gondii* in many of these women suggests that transmission in HIV-infected women can occur in the context of chronic infection. However, Lago and colleagues [511] recently reported a case in which primary infection during pregnancy was documented in the absence of demonstrable IgM antibodies to *T. gondii* in the pregnant woman. This observation suggests that acute infection with *T. gondii* can occur in pregnant HIV-infected women in the absence of a detectable IgM antibody response to the parasite and does not constitute proof of chronic infection. Transmission of *T. gondii* from these chronically infected women would be most likely to occur in the setting of severe immunosuppression, but there are insufficient data at present to test this prediction. Such data would assist in determining the importance of this and other parameters of immunosuppression that place the fetus at risk for congenital *T. gondii* infection.

Noteworthy are the observations that most of the newborns did not have clinical signs of either infection at birth, even though in each case the infant was found to be dually infected with the parasite and HIV. In many of these infants, signs of severe disseminated infection developed within the first weeks or months of life.

Mitchell and colleagues described four young infants, two of whom were siblings, who were dually infected with HIV-1 and *T. gondii* [496]. Their mothers were similarly coinfected. The mother of the first infant had toxoplasmic encephalitis diagnosed at delivery. The other mothers had no clinical evidence of toxoplasmosis but did have *T. gondii* antibodies. The investigators concluded that the mother was the source of the infection in each of the infants. Of interest is that in three of the seven cases (three additional cases were diagnosed after the initial publication) documented at the University of Miami, the diagnosis was not suspected before the patient's death and was made only at autopsy (Mitchell C, personal communication to Remington JS, 1993). Three of the four cases from the original publication are briefly reviewed here as examples of the problem.

#### Case History: Infants 2 and 3

The mother of the siblings with congenital *T. gondii* infection had given birth to five children, four of whom were infected with HIV-1. The siblings with toxoplasmosis were the third and fifth born. AIDS developed in the mother 1 month after the birth of this fifth child, but she had no clinical or tomographic evidence of toxoplasmic encephalitis. She died 8 months later of tuberculosis and bacterial sepsis. An autopsy was not performed. One sibling, born at term and "appropriate for gestational age," was discharged from the hospital at 3 days of age in good condition, only to return at 3 months of age with complications of AIDS. He remained hospitalized until he died at age 6 months. At autopsy, he was found to have disseminated cytomegalovirus infection involving most visceral organs and all lobes of the lung, *T. gondii* pneumonitis, and diffuse CNS toxoplasmosis. The other sibling was a full-term female appropriate for gestational age. She had an unremarkable neonatal course. When

seen at 5 weeks of age, she was in septic shock and emaciated and had severe oral thrush. She died within 1 hour after admission to the hospital. Blood cultures were positive for *Propionibacterium*; the autopsy revealed disseminated candidiasis involving the lungs and esophagus and diffuse intracerebral toxoplasmosis.

### Case History: Infant 4

The patient was an appropriate-for-gestational-age, full-term female infant recognized at birth to be at risk for congenital toxoplasmosis and HIV-1 infection because her mother was known to be seropositive for *T. gondii* and had previously given birth to a child who died of AIDS. Results of examination at birth were normal, but the infant was given expectant treatment for toxoplasmosis with pyrimethamine and sulfadiazine because of the presence of IgM *T. gondii* antibodies in her serum. After an extended course of therapy complicated by hepatitis of unclear etiology, she died; permission for autopsy was denied. This child's mother died of AIDS 3 years later, never having developed clinical toxoplasmosis.

Marty and coworkers [512] described a 22-week pregnant, HIV-infected woman who was observed to have reactivation of her *T. gondii* serologic test titer (from an IgG dye test titer of 5 IU/mL to 400 IU at 1 year later). She had a $CD4^+$ cell count of 90/mm$^3$. An ultrasound examination revealed fetal hydrocephaly, and a therapeutic abortion was performed. The external morphology of the fetus was normal, but the autopsy revealed multiple abscesses in the brain and liver, and *T. gondii* was isolated from amniotic fluid, placenta, liver, spleen, heart, and brain.

### Pathology

Information on pathologic changes in the CNS in fetuses or newborns coinfected with *T. gondii* and HIV-1 is relatively scarce. In three of the cases reported by Mitchell and coworkers, histologic evidence of meningitis included chronic leptomeningeal inflammatory cell infiltrates [496], *T. gondii* cysts, and microglial nodules that suggested an immune response against the parasite were seen in the brain in two cases. Examination of numerous slides from the brain of one infant, who had received treatment for toxoplasmosis, revealed only a single *T. gondii* cyst and no microglial nodules. The brain revealed chronic inflammation and widespread foci of necrosis surrounded by macrophages, lymphocytes, and plasma cells. Gliosis also was present. Immunoperoxidase staining demonstrated *T. gondii* in the CNS of this infant.

Insufficient data are available to estimate how frequently the diagnosis of congenital *T. gondii* infection in these dually infected infants might be suggested by serologic examination. IgM and IgG *T. gondii* antibodies have been demonstrable in some of these infants (Mitchell C and Kovacs A, personal communication to Remington JS, 1993) [498].

### Treatment

**Treatment of the Newborn.** Data on the outcome of treatment of congenital *T. gondii* infection in these newborns are insufficient for any conclusions to be drawn. The diagnosis of coinfection with HIV usually has been made late and often a month or more after birth. Thus at least at present, whether to use drugs directed against HIV in combination with anti-*T. gondii* therapy in the early newborn period does not appear to be a major consideration. Of importance in this regard is that toxicity to the bone marrow may be considerably increased when, for example, zidovudine, pyrimethamine, and sulfadiazine are used together. When the diagnosis in the newborn is suspected or proved, we recommend that the pyrimethamine-sulfadiazine combination be used. Treatment is continued for the first year of life. Data from adults with HIV and *T. gondii* infections suggest that if the $CD4^+$ cell count is maintained at greater than 200 cells/μL with antiretroviral treatment, it may be feasible, after the standard 1-year treatment, to discontinue treatment with pyrimethamine and sulfadiazine.

**Treatment and Primary Prophylaxis in the Human Immunodeficiency Virus- and *Toxoplasma gondii*-Infected Pregnant Women.** Treatment with pyrimethamine-sulfadiazine (and leucovorin) should be started in patients with active toxoplasmosis [513]. Clindamycin may be used as an alternative to sulfadiazine in the combination [514]. Use of pyrimethamine in the first trimester is contraindicated, as discussed earlier. The decision whether to use this drug should be made in consultation with experts.

Until more complete information becomes available on the special factors that predispose to congenital transmission of *T. gondii* in these women, we recommend that primary prophylaxis be used in those with $CD4^+$ T-cell counts of fewer than 200 cells per mm$^3$. The combination agent trimethoprim-sulfamethoxazole, commonly used in these patients to prevent *Pneumocystis* pneumonia, is effective in prevention of toxoplasmic encephalitis in patients with AIDS who can tolerate the drug. Use of this and other drug regimens for *T. gondii* primary prophylaxis is common practice for management of nonpregnant HIV-infected adults who also have chronic *T. gondii* infection [515]. More complete treatment of this subject is beyond the scope of this chapter. For a commentary on this issue in general, the reader is referred to reference [515]. It should be noted, however, that no data are available on whether pyrimethamine-sulfadiazine and pyrimethamine-clindamycin combinations are of comparable efficacy in preventing transmission of *T. gondii* to the fetus.

Of interest in regard to the transmission from mother to her fetus are two cases of CNS toxoplasmosis in HIV-infected pregnant women who gave birth to infants who were not infected with *T. gondii* [516,517].

## DIAGNOSIS

The diagnosis of acute infection with *T. gondii* may be established by isolation of the organism from blood or body fluids, demonstration of the presence of cysts in the placenta or tissues of a fetus or newborn, demonstration of the presence of antigen or organisms or both in sections or preparations of tissues and body fluids, demonstration of antigenemia and antigen in serum and body fluids, specific nucleic acid sequences (e.g., using PCR methods), or serologic tests.

## Diagnostic Methods

### Laboratory Examination

**Cerebrospinal Fluid.** (See also "Serologic Diagnosis in the Newborn" and "Serologic Studies and Polymerase Chain Reaction Assay in Cerebrospinal Fluid; Polymerase Chain Reaction Assay in Urine" later on.) Approximately 4 decades ago, Callahan and colleagues, in reviewing the cerebrospinal fluid changes in 108 patients with congenital toxoplasmosis, stated, "Examination of the CSF affords the most constant significant laboratory examination for the presence of infantile toxoplasmosis [288]". Although the patients studied by these investigators had the most severe form of the disease, this statement is pertinent even today. Despite the fact that cerebrospinal fluid changes in infants with congenital toxoplasmosis are not specific for toxoplasmosis, the demonstration of these changes should lead the physician to consider a diagnosis of toxoplasmosis even in subclinical cases. The findings of xanthochromia and mononuclear pleocytosis in cases of congenital toxoplasmosis also are common in many other generalized infections of the newborn. Almost unique to infants with neonatal toxoplasmosis, however, is the very high protein content of the ventricular fluid. Although in some infants the protein level is just slightly above normal, in others it can be measured in grams per deciliter rather than in milligrams per deciliter [56,328,518]. Alford and associates considered that in most infants with congenital toxoplasmosis who appear clinically normal at birth, a "silent" CNS involvement is present as reflected by persistent cerebrospinal fluid pleocytosis and the elevated protein content (see also the "Central Nervous System" section under both "Pathology" and "Clinical Manifestations") [328].

Increases in protein levels and pleocytosis were not as common in a prospective study performed in France (Desmonts G, unpublished data). The difference probably is due to the difference in method of selection of cases. In the study reported by Alford and associates, only those infants in whom an elevated serum IgM was present at birth were screened for *T. gondii* antibody, and the development of the infection in these infants by the time of birth may have differed significantly from that in the French studies, in which infants were examined because of suspicion of maternal toxoplasmosis acquired during pregnancy. In the French study, the infants, who were infected very close to the time of labor or during labor, may not have had elevated serum IgM levels at birth and therefore would have been missed in the studies in which IgM screening alone was the criterion for case selection.

Persistence of IgM antibodies to *T. gondii* in the cerebrospinal fluid has been observed in some infected infants and may suggest continued active infection. Such persistence of IgM antibodies in the cerebrospinal fluid also has been reported in congenital rubella [519].

Specific IgG antibody formation in the CNS has been demonstrated in infants with congenital toxoplasmosis [520]. Two hundred forty-two examinations were performed in 206 congenitally infected infants as part of the routine cerebrospinal fluid workup. Only three cases (1.8%) had demonstrable local IgG antibody formation in the CNS. *T. gondii* has been detected by PCR assay in cerebrospinal fluid of newborns with congenital toxoplasmosis (see "Polymerase Chain Reaction Assay," later on). Woods and Englund [521] described a newborn with severe congenital toxoplasmosis who had signs of brain destruction and whose cerebrospinal fluid was hazy and xanthochromic, with 302 white blood cells per $mm^3$ and 106 red blood cells per $mm^3$. The differential count revealed 1% neutrophils, 8% mononuclear cells, and 91% eosinophils. The cerebrospinal fluid glucose level was 23 mg/dL, and the cerebrospinal fluid protein level was 158 mg/dL. At the same time, the peripheral blood showed 16% eosinophils (absolute count 432 eosinophils per $mm^3$). Although peripheral blood eosinophilia is common in newborns with congenital toxoplasmosis, as are eosinophilic infiltrations of the pia-arachnoid overlying destructive cortical lesions, eosinophilia has not previously been reported in the cerebrospinal fluid of such newborns.

A newborn whose congenital toxoplasmosis caused hydrocephalus and cerebral atrophy and quadriparesis as a result of spinal cord atrophy had peripheral blood eosinophilia (40%) and markedly abnormal cerebrospinal fluid (13% of 98 white blood cells) (Barson W, personal communication to McLeod R, 1999). Treatment with pyrimethamine and sulfadiazine given to the mother during gestation may diminish manifestations, including cerebrospinal fluid pleocytosis or elevated cerebrospinal fluid protein in the infant [76].

**Blood and Blood-Forming Elements.** Leukocytosis or leukopenia may be present, and early in the course of the infection, lymphocytosis and monocytosis usually are found [6,288,386]. Marked polymorphonuclear leukocytosis frequently reflects suprainfection with bacteria.

Thrombocytopenia is common in infants who have other clinical signs of the infection and in subclinical cases [302,322,491,522], petechiae or ecchymoses may be the earliest clue to this congenital infection [288,293,299,302,491]. Eosinophilia in the newborn period frequently has been observed, and the eosinophils may exceed 30% of the differential white blood cell count.*

### Histologic Diagnosis

Demonstration of tachyzoites in tissues (e.g., brain biopsy, bone marrow aspirate) or body fluids (ventricular fluid or cerebrospinal fluid [289,305,526–529], aqueous humor [530], sputum [531]) establishes the diagnosis of active toxoplasmosis. Unfortunately, it frequently is difficult to visualize the tachyzoite form in tissues or impression smears stained by ordinary methods. Accordingly, the fluorescent antibody technique has been suggested for this purpose [75,532–534]. Because of its greater sensitivity and specificity, the peroxidase-antiperoxidase technique has largely supplanted the fluorescent antibody method [535]. Both methods are applicable to unfixed or formalin-fixed paraffin-embedded tissue sections. The pitfalls in interpretation of results with these methods have been discussed by Frenkel and Piekarski [536]. In

*References 6, 56, 288, 368, 386, 523–525.

the retina, because the retinal pigment epithelium is brown or black, a method that stains the parasites red, rather than brown, has proved useful for detection of the parasites [313]. Histologic demonstration of the cyst form establishes that the patient has toxoplasmosis but does not warrant the conclusion that the infection is acute unless there is associated inflammation and necrosis. On the other hand, because cysts may form early in infection, their demonstration does not exclude the possibility that the infection is still in the acute stages [537].

In the case of acute acquired toxoplasmosis in the pregnant patient, lymphadenopathy may reflect a variety of infectious agents [538]. Distinctive histologic changes in toxoplasmic lymphadenitis enable the pathologist to make a presumptive diagnosis of acute acquired toxoplasmosis [539]. These histologic changes represent the characteristic reaction of the host to the infection, but the organisms themselves are only rarely demonstrable. The histologic signs of infection in other tissues range from areas of no inflammation around cysts to acute necrotizing lesions associated with tachyzoites. The latter are seen almost solely in immunocompromised individuals. None of these changes confirms the diagnosis of toxoplasmosis unless the organism can be demonstrated.

## Isolation Procedures

### General Considerations

Isolation of the parasite from an infant provides unequivocal proof of infection, but unfortunately, such isolation usually takes too long to permit an early diagnosis. *T. gondii* is readily isolated from tissue obtained at autopsy (e.g., brain, skeletal muscle, or heart muscle); the organism may also be isolated from biopsy material from the neonate (e.g., skeletal muscle). In our experience, isolates from congenitally infected infants are most often avirulent for mice, and a period of 4 to 6 weeks is usually required for definitive demonstration of the parasite when this method is used. In cases in which the organism is virulent for mice, the parasite can often be demonstrated in the peritoneal fluid after 5 to 10 days. *T. gondii* has been isolated from body fluids (e.g., ventricular fluid or cerebrospinal fluid [304,516,527,540–546], subretinal fluid [547], and aqueous humor) [548] of infants and adults, and from amniotic fluid [544,549,550]. Isolation from tissues (e.g., skeletal muscle, lung, brain, or eye) obtained by biopsy or at autopsy from older children and adults may reflect only the presence of tissue cysts and thus does not constitute definitive proof of active acute infection. One possible exception is the isolation of *T. gondii* from lymph nodes in older children and adults; such evidence probably indicates relatively recently acquired infection because cysts are rarely found in lymph nodes. Attempts at isolation usually are performed by injection of suspect material into laboratory mice but also may be accomplished by inoculation into tissue culture preparations (see later discussion) [289,545,551,552]. One can observe plaque formation and both extracellular and intracellular parasites in unstained or stained preparations. Abbas found cell cultures less sensitive than mouse inoculation for isolation of the parasite [553]. Thus if cell cultures are used in attempts at primary isolation, it is advisable also to use mouse inoculation when feasible. Tissue culture isolation is quite rapid (usually requiring 1 week or less) and should be used when early isolation is critical for the management of the patient. Because physicians often request that isolation procedures be performed, the following are offered as guidelines for the laboratory.

Specimens should be injected into animals and cell cultures as soon as possible after collection to prevent death of the parasite. Formalin kills the parasite, and freezing may result in death of both tachyzoite and cyst forms. If storage of specimens is necessary, refrigeration at 4° C is preferred. This can maintain the encysted form in tissues, if kept moist, for up to 2 months and prevents death of the tachyzoite for several days. The parasite can survive in blood for a week or longer (see “Transmission” section). For antibody determination, serum may be removed from clotted cord blood or blood obtained later in the newborn period; the clot should be stored at 4° C until the results of serologic tests are known. If results of serologic tests are not diagnostic and the reason for suspecting congenital toxoplasmosis remains, the blood clot should be injected into mice (or tissue culture) in the same way as for any other tissue specimen. Body fluids and heparinized blood can be injected directly, but we prefer to remove the plasma from the formed elements of blood and amniotic fluid, to eliminate the possibility of introducing a majority of *T. gondii* antibodies into the recipient animals. Passively transferred human antibody may interfere with infection of the mice, and thus with isolation of the organisms, and producing false-positive serologic test results in the inoculated animals for 6 weeks or longer [58]. Because the organisms are most likely to reside within white blood cells in patients with parasitemia, the buffy coat layer may be suspended in a small volume of sterile saline and inoculated into mice by the intraperitoneal or subcutaneous route or onto tissue culture.

Biopsy specimens and blood clots may be triturated with a mortar and pestle or tissue homogenizer in a small amount of normal saline before animal or tissue culture inoculation. After trituration, we generally add enough sterile saline so that the suspension can be drawn into a syringe. If connective tissue prevents aspiration through the needle, the suspension can be filtered through several layers of sterile gauze. Depending on the size of the mice, 0.5 to 2 mL is injected intraperitoneally, subcutaneously, or both. For isolation attempts from superficial enlarged lymph nodes, material can be obtained by needle aspiration of the node.

To isolate *T. gondii* from large amounts of tissue (e.g., placenta), we use trypsin digestion (0.25% trypsin in buffered saline, pH 7.2) [66]. The trypsin method makes it possible to isolate both tachyzoite and cyst forms. The former are killed more rapidly by pepsin-hydrochloric acid (HCl) [30]. The tissue is first minced with scissors and passed through a meat grinder or ground in a blender; it is then placed in a volume of trypsin solution (10 to 20 mL of trypsin solution per gram of tissue) and incubated with constant agitation for 1.5 to 2 hours at 37° C. (If the tissue is grossly contaminated, antibiotics may be added both to the digestion fluid and to the tissue digest before injection.) The suspension is passed through

several layers of gauze to remove large particles and then is centrifuged. After the sediment has been washed three or four times in saline to remove trypsin, the digested material is resuspended in saline, and 0.5 to 1 mL is injected both intraperitoneally and subcutaneously into mice. If peptic digestion is desired, the solution is prepared by dissolving 4 g of pepsin (Difco 1:10,000), 7.5 g of sodium chloride, and 10.5 mL of concentrated HCl in water to a volume of 1500 mL. The method described by Dubey also may be used [554].

### Mouse Inoculation

In most countries, it is not necessary to perform serologic testing in laboratory mice to determine if they are infected before they are used in isolation attempts. In areas of the world where normal laboratory mice have been found to be infected, serologic testing of individual mice must be performed before such use. Five to 10 days after intraperitoneal injection, the peritoneal fluid should be examined either fresh or in stained smears (Wright or Giemsa stain) for the presence of intracellular and extracellular tachyzoites (see Fig. 31–1, *A*). Demonstration of the organism is proof of the infection. Mice that die before 6 weeks have elapsed are examined for the presence of the organism in their peritoneal fluid; stained impression smears of liver and spleen also can be examined. If no organisms are found, suspensions of liver, spleen, and brain may be injected into fresh mice. Surviving mice are bled from the tail vein or orbital sinus for serologic testing after 6 weeks but may be bled from the tail vein more often (e.g., at 2-week intervals). (The dye test, agglutination test, IFA test, or ELISA can be used for this purpose.) We prefer to use the agglutination test as a screening method for this purpose because only a single drop of blood from the tail vein can be tested using microtiter plate wells. If antibodies are present, proof of infection must be obtained by demonstration of the parasite. This can be accomplished most easily by examining Giemsa-stained smears of fresh brain for demonstration of cysts (see Fig. 31–1, *E*). Examination of wet preparations of brain tissue may be misinterpreted if done by inexperienced workers; pine pollen has been confused with *T. gondii* cysts and has led to erroneous diagnosis of the infection. Examination is easier under phase microscopy. If cysts are not seen, injection into fresh mice of a suspension of brain, liver, and spleen should be performed to determine whether the parasite is present.

### Tissue Culture

Isolation by tissue culture has been used routinely by Derouin and colleagues, with a high degree of success [549]. They use coverslip cultures of human embryonic fibroblasts (MRC5, bioMérieux, Lyon, France) in wells of 24-well plates (Nunc, Denmark) [552]. The sediment of approximately 10 mL of amniotic fluid is resuspended in 8 mL of minimum essential medium (MEM) supplemented with 10% fetal calf serum, penicillin (5 IU/mL), and streptomycin (50 mg/mL). One milliliter of the suspension is inoculated into each of six cell culture wells and incubated for 72 to 96 hours at 37° C. Thereafter, they are washed with phosphate-buffered saline and fixed with cold acetone. Indirect immunofluorescence is then performed on the coverslip cultures, using rabbit anti-*T. gondii* IgG as the first antibody and fluorescein-labeled rabbit anti-IgG as the second antibody. After the coverslips are mounted onto slides, they are examined for the presence of *T. gondii* by fluorescence microscopy. Parasite division is readily observed in the cells, as is pseudocyst formation; if cells are heavily infected, foci of extracellular parasites may be present. Some workers stain the coverslips with Wright-Giemsa stain or use the immunoperoxidase method to demonstrate *T. gondii* in the cultures. These methods, however, are less sensitive than immunofluorescence for detection of low numbers of parasitized cells.

### Special Considerations

**Placenta.** If congenital toxoplasmosis is suspected in a newborn, either because acute toxoplasmosis was diagnosed during pregnancy in the mother or because clinical signs raise suspicion of this diagnosis in the neonate, approximately 100 g of placenta should be kept without fixative and stored at 4° C until it can be injected into mice. Digestion with trypsin is preferable. This procedure resulted in isolation of *T. gondii* in 25% of placentas obtained from 123 mothers who acquired toxoplasmosis during pregnancy, and in each of these positive cases it was associated with a congenitally infected neonate [540]. Conversely, cases in which infants were proved to be infected, despite the inability to isolate *T. gondii* from their placentas, are rare unless mothers have received treatment during pregnancy [69,555].

Fricker-Hidalgo and colleagues [556] describe an increase in ability to diagnose congenital *T. gondii* infection at birth by combining polymerase chain reaction, study of the placenta, subinoculation of placenta, and serology. The placenta examination by polymerase chain reaction and mouse inoculation increased the sensitivity of the diagnosis of congenital toxoplasmosis at birth from 60% (use of serologic techniques on the newborn's blood only) to 75% (both serologic techniques and placental analysis). The specificity of *Toxoplasma gondii* detection in the placenta was 94.7%. It has been demonstrated in earlier studies that subinoculation studies of the placenta are useful to diagnose infection, and that prenatal treatment reduces the ability to isolate the parasite from the placenta.

**Blood.** *T. gondii* may be isolated from cord or peripheral blood of the newborn [526]. Such isolation should be attempted whenever possible because serologic diagnosis may be uncertain during the first weeks or months of life. In a study of 69 infants with congenital toxoplasmosis, Desmonts and Couvreur isolated *T. gondii* from peripheral blood in 30 (43%) of them (see Table 31–1) [557]. The high incidence (52%) of parasitemia in infants with subclinical infection is noteworthy, as is the overall frequency of parasitemia in congenital cases.

Relatively few positive results were obtained in infants with only neurologic or ocular signs of the disease. This

might be related to the fact that these infants usually are not examined during the first days of life, unlike those with generalized disease or those in whom the possibility of disease is suspected because of prospective studies in their mothers. Seventy-one percent of the positive results were obtained from samples of blood taken during the first week of life. The percentage decreased to 33% when blood for isolation purposes was obtained during the following 3 weeks, and there were no positive results in infants older than 1 month of age [557].

**Saliva.** Levi and coworkers have reported the isolation of *T. gondii* from saliva of 12 of 20 patients, mostly with the lymphadenopathic form of the disease [531]. This report is interesting but requires confirmation. Whether the parasite can be isolated (or demonstrated by PCR assay) from sputum or saliva in the newborn period remains to be determined, but the presence of the organism in the alveoli of the lung suggests that attempts at isolation from such material might prove successful.

**Postmortem Specimens.** *T. gondii* is most easily isolated post mortem from brain specimens from infected infants and from infected infants who die months or years after birth, although it also has been isolated from virtually every organ and tissue of infants with congenital toxoplasmosis. Here again, digestion with either pepsin or trypsin is preferred because it allows for sampling of sufficiently large amounts of tissue. If necessary, brain specimens passed several times through a syringe and a 20-gauge needle can be injected into mice directly without prior digestion. It is noteworthy that isolation of *T. gondii* from the placenta is common in cases in which fetal death has occurred in utero. Although the organisms are regularly isolated from infected fetuses after induced abortion, they usually cannot be isolated from infected macerated fetal tissue that has remained in utero for an extended period of time after the fetus has died.

### Tests of Cell-Mediated Immunity

**Toxoplasmin Skin Test.** At present, the skin test is not used in diagnosis of congenital infection, and no systematic study has been performed to define its potential usefulness for this purpose. It is discussed here for the sake of completeness.

Infection with *T. gondii* results in the development of cell-mediated immunity against the parasite. This may be demonstrated with the toxoplasmin skin test [558], which elicits delayed hypersensitivity. The large-scale use of the skin test, especially in population surveys, has yielded excellent agreement between the results of this test for delayed hypersensitivity and the presence or absence of antibody [558–563]. False-positive skin test results are rare [564]. Delayed skin hypersensitivity to *T. gondii* antigens in cases of acquired infection appears not to develop until months or years after the initial infection [70,168,560,565,566]. For this reason, the skin test appears to be most useful in the diagnosis of chronic (latent) infection; when results are positive, the possibility that the patient had a very recently acquired infection seems remote.

**Antigen-Specific Lymphocyte Responses.** Lymphocyte proliferation to *T. gondii* antigens has been shown to be a specific indicator of prior *T. gondii* infection in adults [233,234,567,568]. This technique has been found useful in establishing the diagnosis of congenital *T. gondii* infection in some infants [480,569,570]. Whereas depressed lymphocyte responsiveness to antigens of the infecting organisms has been reported in infants with congenital cytomegalovirus infection [571,572], congenital rubella [573,574], and congenital syphilis [575], specific cell-mediated immunity appears to develop for most infants with congenital *T. gondii* infection by 1 year of age, although the magnitude of the response is often less than that of their mothers [480]. In one series [480], lymphocyte proliferation to *T. gondii* antigen was both a sensitive (84%) and a specific (100%) indicator of congenital *T. gondii* infection; the sensitivity was similar in asymptomatic (82%) and in symptomatic (88%) infants [480]. Wilson and coworkers concluded that as a diagnostic tool, this method compared favorably with isolation of *T. gondii* and was superior in sensitivity to the IgM IFA test. In the study by Wilson and coworkers, a majority of the patients were not symptomatic or had mild infection, and tests of lymphocyte transformation were performed only once; it is possible that even greater sensitivity would be achieved with repeated testing (as was done with the IgM IFA test). Such repeated testing was done in the cases reported by McLeod and colleagues [570] and Yano and associates [576]. The patients described by McLeod and colleagues [521] had more severe involvement, and a substantial proportion of them did not exhibit lymphocyte blastogenic responses to *T. gondii* antigens in the first month of life. Similar results were reported by Fatoohi and colleagues [265] and by Gublietta and coworkers [577],whereas Ciardelli and colleagues [268] found that greater than 90% of congenitally infected infants less than 90 days of age had detectable T-cell proliferation and IFN-$\gamma$ production in response to *Toxoplasma* antigen. The basis for the differences between these studies is unknown.

**Lymphocyte Activation Markers in the Presence of *Toxoplasma gondii* Antigen.** A study of increased expression of the marker of T-cell activation, CD25, with addition of *T. gondii* antigen to cultures of lymphocytes from congenitally infected infants described lymphocyte recognition in 38 (100%) of 38 congenitally infected infants in the first year of life (see also under "Immunologic Unresponsiveness to *T. gondii* Antigens") [522]. Nine (10%) of 89 uninfected infants, also had values of 7% or greater when tested initially but not when retested later.

## Polymerase Chain Reaction Assay

In 1990, Grover and colleagues described the usefulness of PCR assay for rapid prenatal diagnosis of congenital *T. gondii* infection [578]. In a prospective study of 43 documented cases of acute maternal *T. gondii* infection acquired during gestation, PCR assay correctly identified the presence of *T. gondii* in all five samples of amniotic fluid from four proven cases of congenital infection and

in three of five positive cases from a nonprospective group. Detection of IgM antibodies in fetal blood and inoculation of amniotic fluid into tissue cultures identified the infection in two and four of the nine infants with PCR-positive samples, respectively. Mouse inoculation of blood and amniotic fluid detected seven and six of the nine infants with PCR-positive samples, respectively. No false-positive results were obtained with any of the methods. PCR techniques have subsequently been used successfully on samples of ascitic fluid, amniotic fluid, cerebrospinal fluid, blood, urine, and tissues, including the placenta and brain of infants with congenital toxoplasmosis [75,404,579–592] (see discussion of PCR assay in amniotic fluid and effects of treatment, under "Prenatal Infection") [206,455,592]. Possible reasons for false-negative results include [593] mishandling of the sample before it is received by the laboratory and use of a single-copy target gene that limits the sensitivity and thus is not able to detect the *T. gondii* DNA in the sample. Because PCR assay in amniotic fluid is performed at 18 weeks of gestation by most investigators, reliability of this test performed earlier than 18 weeks of gestation is unknown.

Reischl and colleagues used real-time fluorescence PCR assays to compare results obtained with the more conventional 35-fold repeated B1 gene of *T. gondii* with a newly described multicopy genomic fragment, a 529-base-pair (bp) repeat element, that is repeated more than 300 times in the genome of *T. gondii* [594]. These investigators provided convincing evidence that the 529-bp repeat element provides the advantage of greater sensitivity than that with use of the B1 gene: this 529-bp element is being adopted by a number of reference laboratories using real-time PCR methods. This method is 92% sensitive and 100% specific (Figure 31-19).

Real-time PCR testing combines amplification and detection steps and use of a fluorescence-labeled oligonucleotide probe, making completion of the assay possible in less than 4 hours [175,595,596]. Real-time PCR analysis is useful to quantitate parasite concentration in amniotic fluid (Figure 31-19) [87]. Larger concentrations of parasites in amniotic fluid before 20 weeks of gestation have the greatest risks of severe outcome in the fetus and newborn (Figs. 31–20 and 31–21; Tables 31–19 and 31–20) [87,206].

Perhaps the greatest advance in prenatal diagnosis of *T. gondii* infection in the fetus has been the use of PCR on amniotic fluid without having to resort to a percutaneous umbilical blood sample [77]. PCR testing probably will replace many of the methods described in this section for diagnosis of the infection in the newborn.

### Demonstration of Antigen in Serum and Body Fluids

The ELISA has been used to demonstrate *T. gondii* antigenemia in humans and animals with the acute infection [597–603], and antigen has been demonstrated in cerebrospinal fluid and amniotic fluid of newborns with congenital toxoplasmosis [597]. *T. gondii* antigens also have been demonstrated in urine of a congenitally infected infant by the ELISA [604]. Dot immunobinding also has been used for this purpose [605].

### Demonstration of Antibodies in Serum and Body Fluids

The ultimate usefulness of tests for the diagnosis of toxoplasmosis depends on quality control of commercial kits,

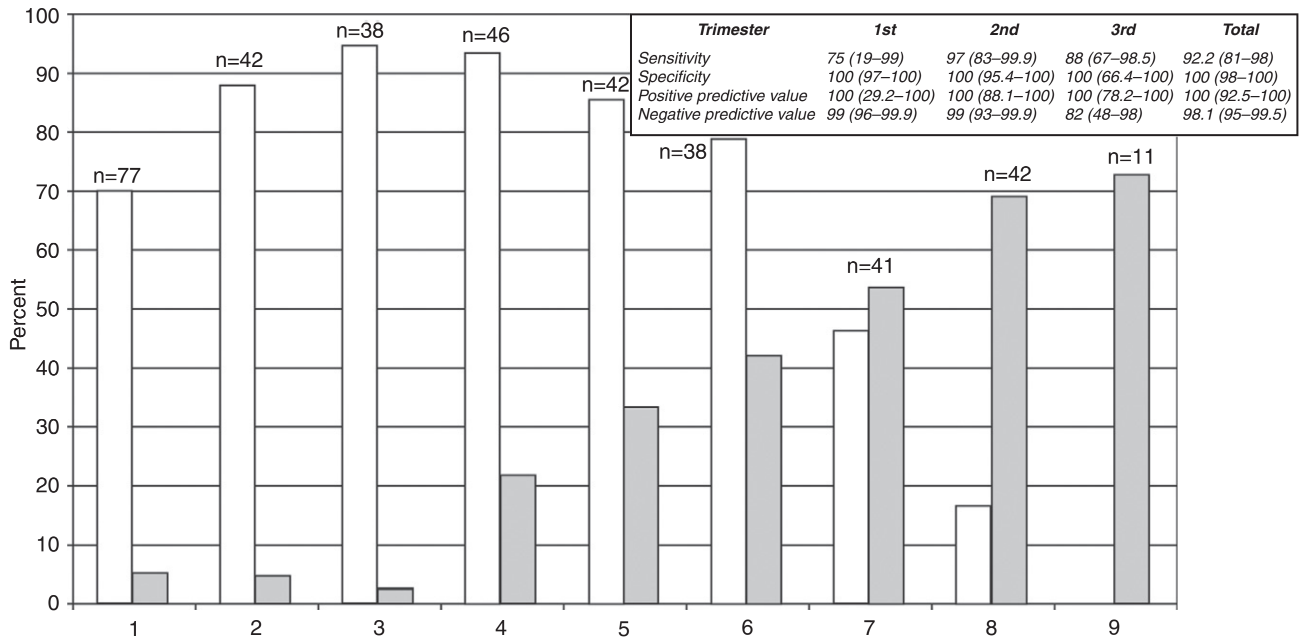

**FIGURE 31–19** Percentage of patients undergoing amniocentesis and cases of congenital *Toxoplasma* infection according to gestational age at maternal seroconverion. (Inset shows Sensitivity, Specificity, and Positive and Negative Predictive Value Estimates for Polymerase Chain Reaction Analysis). Inset data are percentage (95% confidence interval). Open histogram bar is Amniocentesis; Shaded histogram bar is Congenital toxoplasmosis. *(Adapted with permission from Wallon M, Franck J, Thulliez P, Huissoud C, Peyron F, Garcia-Meric P, Kieffer F. Accuracy of real-time polymerase chain reaction for Toxoplasma gondii in amniotic fluid. Obstet Gynecol 115(4):727–733, 2010.)*

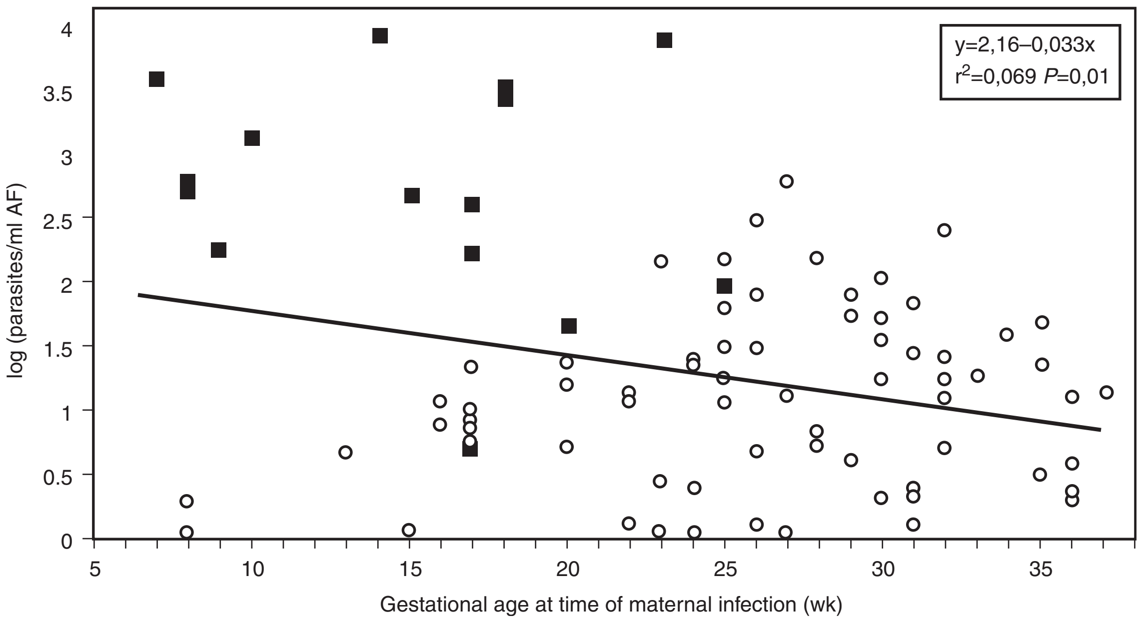

**FIGURE 31–20** Correlation between *Toxoplasma* concentrations in amniotic fluid (AF) samples and gestational age at maternal infection for the 86 cases. Severity of the infection is represented in each case by ■ if severe signs of infection were recorded or by ○ if no or mild signs were observed. In general, the earlier the mother is infected, the higher the parasite numbers in amniotic fluid. Some babies who had relatively low numbers of parasites were severely infected, and many babies who had relatively high numbers of parasites were not severely infected. *(Data from Romand S, et al. Usefulness of quantitative polymerase chain reaction in amniotic fluid as early prognostic marker of fetal infection with* Toxoplasma gondii. *Am J Obstet Gynecol 190:797–802, 2004.)*

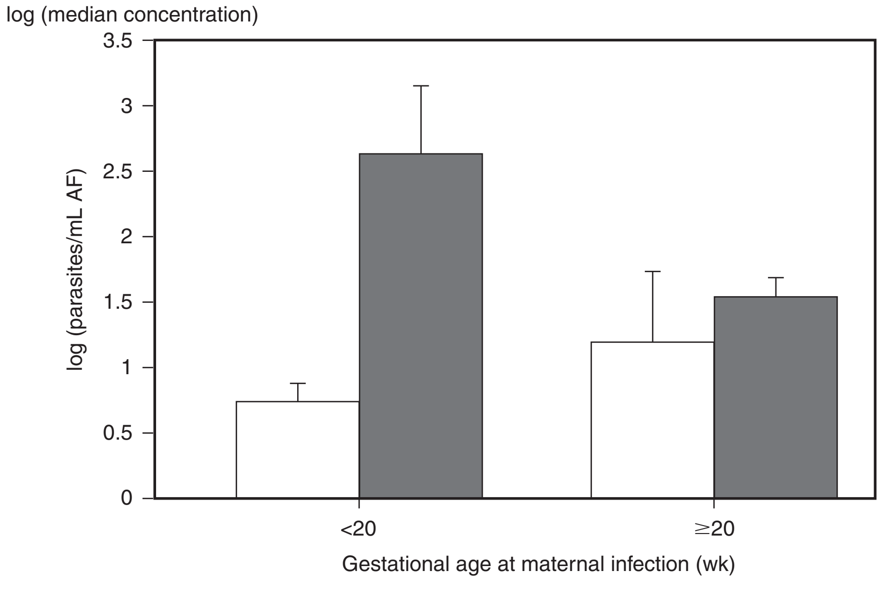

**FIGURE 31–21** Comparison of median (interquartile range) parasite concentrations in AF between cases with subclinical infection (*unshaded bars*) and cases with infectious sequelae (*shaded bars*) for maternal infections acquired before or after 20 weeks of gestation. Clinical status was recorded either at birth or following fetal death (at fetopathologic examination). *(Data from Romand S, et al. reliability of the laboratory performing the test, and accuracy and skill of persons interpreting results according to the specified clinical circumstance.

The most common serologic tests in use at present for diagnosis of *T. gondii* infection and toxoplasmosis are the Sabin-Feldman dye test [10], the indirect hemagglutination (IHA) test [127], the IFA test [606], the agglutination test [607], the ELISA [608–611], and the immunosorbent agglutination assay (ISAGA) [612–614]. Certain serologic methods are of little help in diagnosing congenital toxoplasmosis. This is especially true for some CF or IHA tests [606]. Results with these tests may be weakly positive or even negative in a newborn with congenital toxoplasmosis, and in the infant's mother. The diagnosis of acute acquired toxoplasmosis may be established by the demonstration of rising serologic test titers [163]. A stable high titer, however, may have been reached by the time the patient is first seen by a physician. Because high titers (e.g., 300 to 1000 international units [IU]) may persist for many years after acute infection [96] (Figs. 31–22 and 31–23) and are present in the general population, a single high serologic test titer in any one method does

*In considering the results of this study, it is important to note that the numbers of women with acute acquired infection differ substantially for each group. This is in part due to the time when women first seek prenatal care. Of note is that the intervals between date of maternal infection and amniocentesis also diminish with time during gestation at which infection was acquired, after 16 weeks of gestation.*

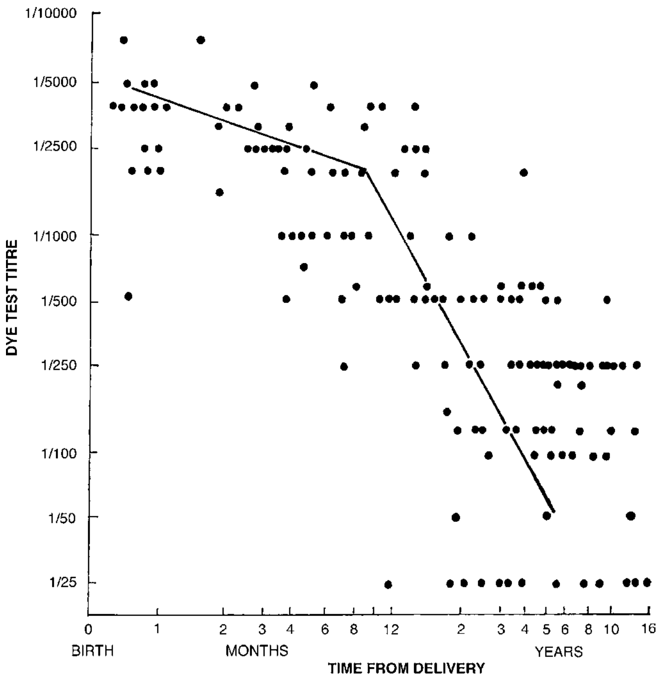

**FIGURE 31–22** Dye test titers in 117 mothers of children with congenital toxoplasmosis in relation to time since delivery. *(Data from Couvreur J, Desmonts G. Congenital and maternal toxoplasmosis. A review of 300 congenital cases. Dev Med Child Neurol 4:519–530, 1962.)*

not constitute conclusive evidence that a clinical illness is due to toxoplasmosis.

**Sabin-Feldman Dye Test.** The Sabin-Feldman dye test is based on the observation that when living organisms (e.g., from the peritoneal exudate of mice) are incubated with normal serum, they become swollen and stain deeply blue when methylene blue is added to the suspension [10]. Parasites exposed to antibody-containing serum, under the same conditions, appear thin and distorted and are not stained when the dye is added. This is due to lysis of the organisms [615]. The membrane is disrupted because of activation of the complement system [616]. The titer reported is that dilution of serum at which half of the organisms are not killed (stained) and the other half are killed (unstained). (The stain is not required. Differentiation of lysed from nonlysed organisms may be readily accomplished under phase microscopy.) The World Health Organization (WHO) has recommended that titers in most serologic tests be expressed in IU/mL of serum, compared with an international standard reference serum, which is available on request from the WHO [617].

**Agglutination Test.** The agglutination test [618,619] is available commercially in Europe and has been evaluated by a number of investigators [620–625]. The test employs whole parasites that have been preserved in formalin. The method is very sensitive to IgM antibodies. Nonspecific agglutination (apparently related to "naturally" occurring IgM *T. gondii* agglutinins) has been observed in persons devoid of antibody in the dye test and conventional IFA test [626]. These natural IgM antibodies do not cross the placenta but are detected at low titers as early as the second

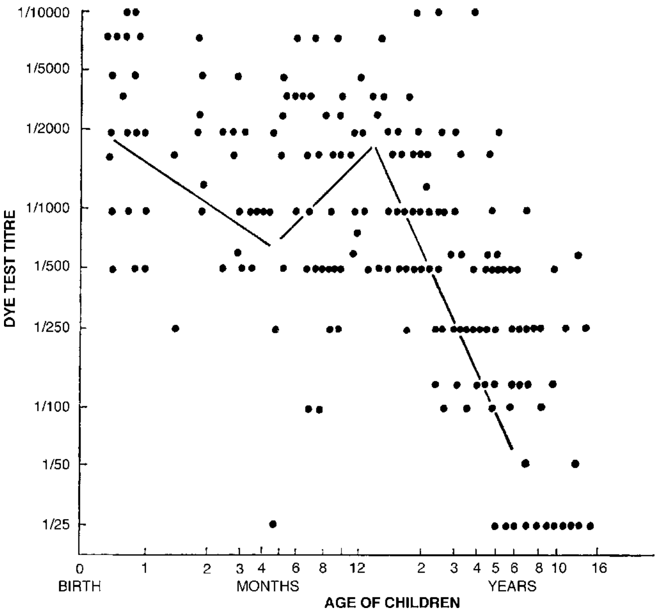

**FIGURE 31–23** Dye test titers in 119 children with congenital toxoplasmosis in relation to age. *(Data from Couvreur J, Desmonts G. Congenital and maternal toxoplasmosis. A review of 300 congenital cases. Dev Med Child Neurol 4:519–530, 1962.)*

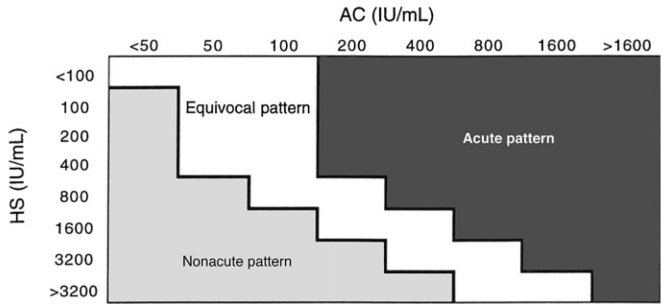

**FIGURE 31–24** Interpretation of HS/AC test results. This differential agglutination test was performed as described in the text. *(Data from Dannemann BR, et al. Differential agglutination test for diagnosis of recently acquired infection with* Toxoplasma gondii. *J Clin Microbiol 28:1928–1933, 1990.)*

month of life. They do not develop in infants with maternal IgG antibody to *T. gondii*, however, so long as IgG antibody is present. False-positive results due to these natural antibodies may be avoided [627]. When they are, this test is excellent for wide-scale screening of pregnant women because it is accurate, simple to perform, and inexpensive [627,628]. A method that employs latex-tagged particles also may become available commercially [629–631].

**Differential Agglutination Test.** A chemical alteration of the outer membrane of the parasite led to the development of a unique differential agglutination method (HS/AC test) that is very useful for helping to differentiate between acute and chronic infections in the pregnant patient [613,619,632,633]. The differential agglutination test compares titers obtained with formalin-fixed tachyzoites (HS antigen) with those obtained with acetone- or methanol-fixed tachyzoites (AC antigen) [613,619]. The AC antigen preparation contains stage-specific antigens that are recognized by IgG antibodies early during infection; these antibodies have different specificities from those found later in the infection [634]. Guidelines for interpretation of results for this test are shown in Figure 31–24. In the appropriate clinical setting, this method is useful for diagnosis of the acute infection using a single serum sample from the patient [613]. In practice, to assist with a clinical decision, it is important to take into consideration the results of other serologic tests along with those found in the HS/AC test. It is our practice to use the HS/AC test only in adults, and only in those who have IgG and IgM antibodies to *T. gondii* and in whom there is a question about whether the infection was recently acquired.

In the study by Dannemann and coworkers in which a single serum specimen was tested in each patient, the HS/AC test correctly identified all of the pregnant and almost all (31 of 33) of the nonpregnant patients with recently acquired toxoplasmic lymphadenopathy or asymptomatic infections [613]. Each of the seven women in their study who seroconverted during gestation had an acute pattern in the HS/AC test within 0 to 8 weeks after seroconversion in the dye test. Thirteen percent of 15 women who had been infected for at least 2 years had an acute pattern, but the wide range in duration of time from original infection (2 to 14 years) did not allow for an estimate of when the pattern in the HS/AC test changed from an acute to a nonacute pattern.

**Conventional Indirect Fluorescent Antibody Test.** In the conventional IFA test, slide preparations of killed *T. gondii* are incubated with serial dilutions of the patient's serum. If a specific reaction between the antigenic sites on the organisms and the patient's antibody occurs, it can be detected by a fluorescein-tagged antiserum prepared against serum immune globulins. A positive reaction is detected by the bright yellow-green fluorescence of the organisms seen on examination by fluorescence microscopy. In general, qualitative agreement with the dye test and IFA test has been excellent [606]. Despite the claims of many workers, reliable and reproducible quantitative titers frequently are difficult to obtain. To permit valid comparisons of results from different laboratories that express their titers as the last positive serum dilution, it should be noted that, depending on the laboratory, the dye test may vary in sensitivity, ranging between 0.1 and 0.5 IU/mL for the 50% endpoint. Thus a positive result for this test on a serum with a titer of 1000 IU/mL could be reported as 1:2000 or 1:10,000 in the dye test. The range is even greater with the IFA test.

Although most workers consider the IFA test to equal the dye test in specificity, false-positive results occur with some sera that contain antinuclear antibodies [635]. For this reason, in patients with connective tissue disorders (e.g., systemic lupus erythematosus), a dye test or ELISA can be performed to document a positive result on IFA testing.

To avoid misinterpretation of the polar staining of organisms that is due to naturally occurring IgM antibodies [636,637], the fluorescein-tagged conjugate should be only anti-IgG [638].

**Conventional Enzyme-Linked Immunosorbent Assay.** The ELISA technology has largely replaced other methodologies in the routine clinical laboratory. It has been used successfully to demonstrate IgG, IgM, IgA, and IgE [639,640] antibodies in the pregnant woman, fetus, and newborn [610,641,642]. Most workers have employed an enzyme-conjugated antibody directed against human IgG [643–645] or against total immunoglobulins [646–650]. Titers in the IgG ELISA correlated well with titers in the dye, IHA, IFA, and CF tests in some studies [649] but not in others [650,651]. Commercial kits are widely available for detection of IgG or IgM antibodies. Their reliability for detection of IgM antibodies varies considerably, however, and false-positive results have been a serious problem [652,653].

**Capture Enzyme-Linked Immunosorbent Assay.** The capture ELISA is routinely employed by many laboratories for demonstration of IgM [158,608,624] and IgA [641,642,651] *T. gondii* antibodies in the fetus, newborn, and pregnant patient. In appropriately standardized methods (commercial kits), the IgA ELISA appears to be more sensitive than the IgM ELISA or IgM ISAGA for diagnosis of the infection in the fetus and newborn. IgA antibodies may persist for 8 months or longer in congenitally infected infants [610,642,608,640]. Demonstration of IgA *T. gondii* antibodies in an adult with early acute acquired infection is comparable to demonstration of IgM antibody, although IgA antibody may appear somewhat later than IgM antibody. In the adult, IgA *T. gondii* antibodies usually disappear earlier than do IgM antibodies, but as with the latter, IgA antibody titers may remain positive for a year or longer. Very high titers in either ELISA appear to correlate with more recent onset of the infection. Many cases in adults have been observed in which the IgM ELISA and HS/AC (see earlier) test results were positive and the IgA ELISA result was negative. We and others have not found the IgA test to be useful for diagnosis in most cases of acute infection in pregnant women [654].

**IgG/IgM Western Blot Analysis for Mother-Infant Pairs.** In the infected fetus, IgG and/or IgM serum antibodies produced against antigenic determinants of *T. gondii* may differ from those recognized by the IgG and/or IgM serum antibodies of the mother [283,655,656]. The fact that Western blot analysis can be used to demonstrate these differences in mother-baby pairs has led to the development of commercial kits for this purpose. The potential of this method for diagnosis of infection in the fetus and newborn is highlighted by the observations of Tissot-Dupont and colleagues, who prospectively studied IgG, IgM, and IgA Western blots in sera of 126 infants born to mothers who had acquired *T. gondii* infection during gestation [657]. Conventional serologic tests were performed during the first year of life, and Western blot analyses were performed on day 0 and/or day 5 and at 1 and 3 months of age. Serologic follow-up evaluation revealed that 23 of the infants had the congenital infection and that the remaining 103 infants were not infected. Although the Western blot method proved more sensitive than the IgM ISAGA (86.9% versus 69.6%, respectively) (specificity of both methods was greater than 90%), the sensitivity increased to 91.3% when both tests were performed in combination. IgA blots were least sensitive. Similar results were reported by Pinon and associates in a collaborative study involving laboratories in the European Community Biomed 2 program [656].

Cases of congenital infection have been observed in the first months of life in infants in whom results of the IgM antibody tests were negative and the Western blot analysis result was positive. The Western blot method on mother-baby pairs may yield negative results during the first days of life in the infected newborn, however, and a demonstrable positive result in infected babies may not appear for weeks or even 2 or more months after birth [283]. Prenatal treatment during gestation and/or treatment of the infant may result in false-negative results on Western blot analysis. It is important that the Western blot method for mother-baby pairs always be used in combination with other serologic tests for IgG, IgM, and IgA antibodies. Western blot analysis for diagnosis of the congenital infection probably is most useful in those newborns in whom IgA and/or IgM *T. gondii* antibodies are not demonstrable in conventional serologic tests but whose mothers had a definite or highly likely diagnosis of acquired infection during gestation. It should be emphasized that no serologic test, performed singly or in combination, or the Western blot method allows for the diagnosis of the congenital infection in all cases. An example of IgG and IgM Western blots from a mother-baby pair is shown in Figure 31–25 [283]. Additional recent studies have suggested that comparisons of patterns of antibody response from mothers and their infants in Western blots are useful in establishing the diagnosis of congenital toxoplasmosis [658–660].

**IgG Avidity Assay.** The avidity assay should be used in conjunction with other serologic tests (i.e., *T. gondii*-specific IgG, IgM, IgA, IgE, and AC/HS) [88,89,283]. The method is most useful (and should be performed) in women in the first 16 weeks of gestation in whom IgM antibodies are found. It also is useful late in gestation to determine whether infection was acquired 4 or more months earlier, thereby allowing for an estimate of the rate of fetal infection at a given time during gestation. Testing for the avidity of antibodies against *T. gondii* stems from the knowledge that after primary antigenic stimulation, antibody-binding avidity (affinity) for an antigen is initially low but increases thereafter. IgG antibodies that are present owing to prior antigenic stimulus most often are of high avidity; this pertains to the secondary antibody response as well. (For a review, the reader is referred to the article by Hedman and colleagues) [661]. The most widely used method is one that employs the hydrogen bond-disrupting agent urea, which preferentially dissociates complexes formed by low-affinity antibodies. An avidity "index" may be determined as the percentage of antibodies that resist elution by 6M urea (e.g., in an ELISA plate). The method has been used by numerous investigators in an attempt to differentiate between recently acquired infection and infection acquired in the more distant past [662–666].Commercial

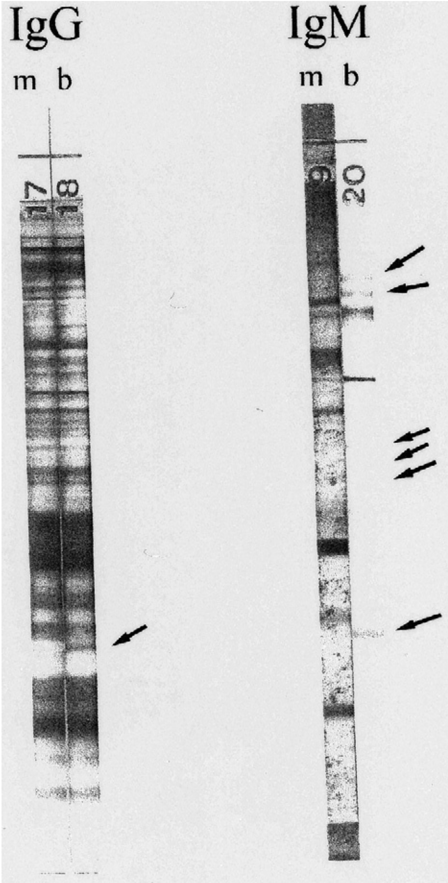

**FIGURE 31–25** IgG and IgM Western blots of serum from a mother (m) and her newborn infant (b). Sera were drawn from mother and baby when the baby was 2 days of age. Arrows point to bands in the blot of the serum of the baby that were not present in the corresponding blot of the serum from the mother. Serologic test results in the mother were as follows (results in the baby are in parentheses): dye test, 600 IU (300 IU); IgM ELISA, 2.9 (IgM ISAGA, 3), both positive; IgA ELISA, 1.8 (1.3), both positive; IgE ELISA, negative (positive); PCR assay in placental tissue, negative. *Toxoplasma* was isolated from the placental tissue. *ELISA*, enzyme-linked immunosorbent assay; *IgA*, *IgG*, *IgM*, immunoglobulins A, G, M; ISAGA, immunosorbent agglutination assay; *PCR*, polymerase chain reaction. *(Adapted from Remington JS, Thulliez P, Montoya JG. Recent developments for diagnosis of toxoplasmosis. J Clin Microbiol 42:941–945, 2004.)*

kits are available in Europe and approval is currently under consideration in the U.S. [667].

At present, despite the many publications using the ELISA format, consensus on a standard procedure is lacking. Thus each investigator has had to define what constitutes a low-or high-avidity or equivocal result. What is generally agreed on is that a low avidity cannot be interpreted to mean that the patient has had a recently acquired infection because low-avidity antibodies may persist for more than 5 months, depending on the method used. A high-avidity result in the first trimester (or up to 16 weeks of gestation depending on the kit used), however, virtually rules out a recently acquired infection. Unfortunately, for all methods thus far reported, the equivocal range is broad, and a result in this range requires additional testing in a reference laboratory.

For diagnosis in the pregnant woman, the avidity method is most useful when used in the first 12 to 16 weeks of gestation because a high-avidity result late in gestation does not rule out an infection acquired in the first trimester or earlier. With the method used in their laboratory, Lappalainen and colleagues [668] reported that the predictive value of a high-avidity test result for excluding infection in the prior 5 months was 100%. In the Palo Alto laboratory, a high-avidity result obtained by an ELISA method during the first 16 weeks of gestation essentially excludes an infection acquired within the prior 4 months. Jenum and associates [669] concluded from their results with the avidity method that acquisition of *T. gondii* infection in early pregnancy can be excluded on the basis of results with a single serum sample collected in the first trimester. By confirming latent infection on the basis of a high-IgG avidity result early during gestation, the need to collect a second serum sample is eliminated. Antibiotic treatment has been suggested to affect the kinetics of IgG avidity maturation [670] and thereby prolong the duration of detectable low-avidity antibodies. It has been recently demonstrated, however, that treatment with spiramycin had no influence on the increase of the avidity index in pregnant women [671]. The avidity test is an excellent adjunctive method for ruling out infection acquired during the first 12 to 16 weeks of gestation [668,672–674].

The avidity assay is especially useful when only a single sample of serum has been obtained in which IgM *T. gondii* antibodies are present, and when the AC/HS test gives an acute or equivocal pattern. A recent study compared results obtained in an IgG avidity test with those obtained in the IgM ELISA and AC/HS test for sera that had equivocal or positive IgM ELISA or AC/HS test results [89]. A substantial proportion (e.g., 42 of 81 serum samples [52%] with high titers of *T. gondii* IgG antibodies) had high-avidity test results. Comparison of IgG avidity and differential agglutination test results also showed that 31 of 53 sera (59%) with equivocal and 4 of 33 sera (12%) with acute AC/HS test results had high avidity (i.e., were from women infected 4 or more months earlier). In 69 of 93 samples (74%) with positive or equivocal IgM ELISA results, 52 (56%) had high-avidity antibodies [88,89]. Of 87 (70%) samples with acute or equivocal AC/HS test results, 35 (40%) had high-avidity antibodies. Of 40 women given spiramycin in the first trimester in an attempt to prevent congenital transmission, 7 (8%) had high-avidity antibodies and thus did not require treatment. These women would not have required treatment with spiramycin if the avidity test result were known at the time.

Performance of the avidity test in the first 12 to 16 weeks of gestation has the potential to markedly decrease the need for obtaining follow-up sera and thereby reduce costs, to make unnecessary the need for PCR on amniotic fluid and for treatment of the mother with spiramycin, to remove the anxiety experienced by pregnant patients who are told that further testing is needed, and to decrease unnecessary abortions. Table 31–21 [283] shows results in the literature with avidity tests. In addition, it is important to note that confirmatory serologic testing in a reference laboratory with communication of results and correct interpretation of these results to the patient's physician by an expert decreased rates of unnecessary

**TABLE 31–21** Usefulness of High-Avidity Test Results in IgM-Positive First-Trimester Pregnant Women

| Patient No.* | Gestational Age (wk) | Dye Test (IgG) | IgM | Avidity |
|---|---|---|---|---|
| 73 | 9 | 256 | Positive | High |
| 58 | 12 | 512 | Positive | High |
| 17 | 12 | 256 | Positive | High |
| 74 | 12 | 1024 | Positive | High |

**The high-avidity test result in each of these pregnant women reveals that they were infected before gestation. Without the avidity test results, the positive IgM antibody tests might have been interpreted as showing that the patients had acquired the infection during gestation.*
*IgM, immunoglobulin M.*

abortions by about 50% among women with positive IgM *Toxoplasma* antibody test results reported by outside laboratories [675].

### Demonstration of Specific Immunoglobulin M Antibodies

A positive serum IgM test alone cannot be used to establish the diagnosis of any form of toxoplasmosis in the older child and adult. A positive result on IgM serologic testing in the fetus and in the newborn in the first days of life usually is diagnostic of the infection if contamination of fetal or newborn blood with maternal blood has not occurred. The validity of a positive IgM test result in this setting may be checked by repeating the test 3 to 4 days later. Because the half-life of IgM is short, the repeat testing will reveal either a highly significant drop in titer or, more commonly, a negative result that reveals the original positive titer to have been a "false positive." Also, isolated false-positive *T. gondii*-specific IgM test results have been noted with other fetal infections (Remington JS and McLeod R, unpublished data).

**IgM Fluorescent Antibody Test.** The IFA test has been adapted for the demonstration of IgM antibodies to *T. gondii*, and the method has been successfully used to establish acute congenital and acquired infections [328,618,676–682]. The use of IgM antibody for diagnosis of congenital infection stems from the discovery in 1963 by Eichenwald and Shinefield [683] that the fetus is able to produce IgM-specific antibody. Critical to this method is the choice of an antiserum that is specific for IgM [538,684]. Serious and misleading errors related to the use of antisera that have specificity not only for IgM but also for IgG have been reported in the literature.

Failure to demonstrate IgM antibodies in the IgM IFA test in sera from some patients with the acute acquired infection has been shown to be due to an inhibitory effect of high titers of IgG antibodies to *T. gondii* in these sera [685,686]. This problem may be avoided by removal of the IgG before performance of the IgM IFA test. Commercial kits are available for this purpose.

The presence of IgM antibodies in cord serum or in serum obtained from the neonate is evidence of specific antibody synthesis by the infected fetus *in utero*. Maternal IgM antibodies do not normally pass the placental barrier, as do maternal IgG antibodies. The IgM IFA test was the first test designed to make an early diagnosis of congenital toxoplasmosis by distinguishing between passively transferred maternal antibodies and the response of the fetus and neonate to infection [677]. The test also has been successfully used to detect active acute acquired toxoplasmosis [163,539,687–689]. After acute acquired infection, the IgM IFA test titer may rise rapidly (and at times earlier than titers in the dye test or conventional IFA test) to high levels [687]. The titer usually declines, and the antibodies may disappear within several months; in some patients, however, the IgM IFA test result has remained positive at a low titer for several years. IgM antibodies to *T. gondii* may not be demonstrable in immunodeficient patients with acute toxoplasmosis and in patients with isolated active ocular toxoplasmosis. Only 25% to 50% of congenitally infected infants have *T. gondii*-specific IgM antibodies demonstrable by IgM IFA tests [480,608,684]. With two qualifications, demonstration of IgM antibodies to *T. gondii* in the serum of a newborn should be considered as diagnostic of congenital toxoplasmosis. First, if cord serum is tested, or if the serum is obtained in the early newborn period in an infant during whose delivery a placental "leak" occurred, which enabled maternal blood to mix with that of the infant, a false-positive result could occur in any serologic test for IgM, IgA, or IgE antibodies. This possibility can be investigated by performing the test on the mother's serum. If the mother's serum is negative for IgM antibodies and the infant's serum is positive, the infant is infected. If both mother and infant sera are positive, the infant should be tested again several days later; a marked fall in the IgM IFA test titer will have occurred if the IgM was maternally acquired because the half-life of IgM is only approximately 5 days [690,691]. If the IgM IFA test titer in the infant remains high or is rising, it is diagnostic of infection.

The second qualification is the presence of rheumatoid factor. False-positive IgM IFA test results may occur in sera that contain rheumatoid factor [692]. Rheumatoid factor may be present not only in adults but in infected newborns as well [329,693], purportedly as a result of an IgM immune response of the fetus in utero to passively transferred maternal IgG. After treatment of sera containing rheumatoid factor with heat-aggregated IgG, false-positive IgM IFA test titers become negative. By contrast, titers in cases of acute congenital or acquired toxoplasmosis are unaffected by this treatment. Thus treatment with heat-aggregated IgG or other commercially available adsorbent can be used to differentiate false-positive IgM IFA test titers related to rheumatoid factor from those related to specific IgM antibody to *T. gondii*. The incidence of rheumatoid factor in sera of infants with congenital toxoplasmosis is unknown. All infants who respond positively in the IgM IFA test should be tested for rheumatoid factor as well.

**IgM Enzyme-Linked Immunosorbent Assay.** The double-sandwich IgM ELISA for detection of IgM antibodies to *T. gondii* was developed by Naot and Remington and colleagues [158,608,609]. At present it is the most widely used method for demonstration of IgM antibodies

to *T. gondii* in adults, the fetus, and newborns. In contrast with the conventional method in which the wells of microtiter plates are coated with antigen, the wells are coated with specific antibody to IgM. The IgM ELISA is more sensitive than the IgM IFA test for diagnosis of the recently acquired infection, and serum samples that test negative in the dye test but that contain either antinuclear antibodies or rheumatoid factor and thus cause false-positive results in the IgM IFA test also test negative in the double-sandwich IgM ELISA. This latter observation is attributed to the fact that serum IgM fractions are separated from IgG fractions during the initial step in the IgM ELISA procedure.

The double-sandwich IgM ELISA also is useful for diagnosis of congenital *T. gondii* infection [608]. Results of the double-sandwich IgM ELISA were positive in 43 of 55 serum samples (72.7%) from newborns with proven congenital *T. gondii* infection, whereas IgM IFA test results were positive in only 14 (25.4%) of these samples. Of the sera obtained from the infected newborns during the first 30 days of life, 81.2% were positive in the double-sandwich IgM ELISA, whereas only 25% were positive in the IgM IFA test. Use of the double-sandwich IgM ELISA avoids false-positive results related to rheumatoid factor and false-negative results related to competition from high levels of maternal IgG antibody that occur with the IgM IFA test. A number of modifications of the method have been described [365,694–703]. The double-sandwich IgM ELISA is superior to the IgM IFA test for diagnosis both of acute acquired and congenital *T. gondii* infections.

**Immunosorbent Agglutination Assay for Demonstration of IgM, IgA, and IgE Antibodies.** The ISAGA [612,614,652,701–703] is widely used by investigators because it combines the advantages of both the direct agglutination test and the double-sandwich (capture) ELISA in its specificity and sensitivity for demonstration of IgM, IgA, and IgE [614] antibodies to *T. gondii*. The ISAGA does not require use of an enzyme conjugate; it is as simple to perform as the direct agglutination test and is read in the same manner as for that test. Use of the ISAGA avoids false-positive results related to the presence of rheumatoid factor and/or antinuclear antibodies in serum samples. A commercial kit for IgM antibodies is available (bioMérieux).

The ISAGA is more sensitive and more specific than the IgM IFA and the IgM ELISA [704,705], and has been used effectively for diagnosis of congenital infection [706]. Specific IgA antibodies in the ISAGA test indicated congenital toxoplasmosis in three infants in the absence of associated IgM antibodies [707]. Pinon and coworkers found IgA antibodies in serum and cerebrospinal fluid of seven cases of congenital toxoplasmosis in the neonatal period [705,708].

Because of its high sensitivity, the ISAGA detects IgM antibodies earlier after the acute acquired infection (e.g., 1 to 2 weeks) than do other tests for IgM antibody. This sensitivity also results in the longest duration of detection of IgM antibody after infection. The method has been standardized by the recognition of this greater sensitivity to provide greater diagnostic power during early infections in adults [704]. Pinon and coworkers [614] and Wong and associates [639] have found the IgE ISAGA to be useful for diagnosis of acute acquired infection in the pregnant woman and in the congenitally infected newborn. Its advantage is related to the early rise in titers of IgE antibodies and IgM and IgA antibodies and the much earlier disappearance of IgE antibodies. In the study by Pinon and coworkers, IgE antibodies in the adult persisted for less than 4 months. This test has been available in only a few specialty laboratories. As is true for appropriate interpretation of all other serologic tests for diagnosis of the acute infection, it should be used only in combination with other serologic methods [633,703].

**The Problem of False-Positive *Toxoplasma gondii*-Specific IgM Tests.** *Toxoplasma* IgM test kits are not subject to standardization in the United States, and a substantial proportion of them do not function reliably [653]. Not only is the lack of reliability of such test kits a problem, but use of results in the IgM assays to guide care of the pregnant woman by obstetricians in the United States, and probably elsewhere as well, is not always well informed. For example, Jones and associates [709] reported that 364 of 768 (47%) American College of Obstetrics and Gynecology (ACOG) members responded to a survey regarding their knowledge of toxoplasmosis in pregnant women and related OB-GYN practices. In the previous year, 7% diagnosed one or more cases of acute toxoplasmosis, and only 12% indicated that a positive *Toxoplasma* IgM test might be a false-positive result. Only 11% recalled an advisory sent to all ACOG members in 1997 by the FDA alerting them that some *Toxoplasma* IgM test kits have false-positive results. Sixty-seven percent of respondents were against universal screening of pregnant women for *T. gondii* infection [709]. If obstetricians are carefully educated on the subject, medical care offered to pregnant women would be greatly improved. A positive IgM test alone can never be used to establish the diagnosis of any form of toxoplasmosis.

**Median and Variability of Duration of Positive *Toxoplasma gondii* IgM Antibody Results Measured by Immunofluorescence Testing and ISAGA.** Gras and coworkers [710] from London and Lyon studied a cohort of 446 *Toxoplasma*-infected pregnant women to determine the median and variability of the duration of positive *T. gondii* IgM antibody results measured by an immunofluorescence test (IFT) and an immunosorbent agglutination assay (ISAGA). IgM antibodies were detected for longer using the ISAGA (median, 12.8 months; interquartile range [IQR], 6.9 to 24.9) than the IFT (median, 10.4; IQR, 7.1 to 14.4), but the variability among persons in the duration of IgM positivity was greatest with ISAGA. IgM-positive results persisted beyond 2 years in 27.1% (ISAGA), and 9.1% (IFT) of women. These investigators concluded that variation in the duration of IgM response measured by ISAGA and IFT limits their usefulness for predicting the timing of infection in pregnant women. Nonetheless, they concluded that measurement of IgM and IgG antibodies in cross-sectional serosurveys offers a useful method for estimating the incidence of *T. gondii* infection.

## GUIDELINES FOR EVALUATION OF THE NEWBORN WITH SUSPECTED CONGENITAL TOXOPLASMOSIS

Guidelines for evaluation of the newborn of a mother who acquired her infection during gestation to confirm or rule out the diagnosis of congenital *T. gondii* infection are shown in Table 31–22.

### Serologic Diagnosis of Acquired *Toxoplasma* Infection in the Pregnant Woman

The presence of a positive titer (except for the rare false-positive results mentioned earlier) in any of the serologic tests discussed earlier establishes the diagnosis of *T. gondii* infection. Because titers in each of these tests may remain elevated for years, a single high titer does not indicate whether the infection is acute or chronic, nor does it necessarily mean that the clinical findings are due to toxoplasmosis. Before a diagnosis of acute *T. gondii* infection or toxoplasmosis can be made by means of serologic tests, it is necessary to demonstrate a rising titer in serial specimens (either conversion from a negative to a positive titer or a rise from a low to a significantly higher titer) [163,711]. Because in the United States the diagnosis is frequently considered relatively late in the course of the patient's infection (Table 31–23), serologic test titers (e.g., dye test, IFA test, or ELISA) may have already reached their peak at the time the first serum is obtained for testing. The IgM IFA test, IgM ELISA, IgM ISAGA, and tests for IgA and IgE antibodies and IgG avidity appear to be of considerable help in these circumstances.* The most important fact for the clinician is that any patient with a positive IgG titer and a positive IgM IFA or IgM ELISA titer must be presumed to have recently acquired infection with *T. gondii* and be tested further in a reference laboratory [652,712]. Most mothers of children with congenital toxoplasmosis are unable to recall being ill during pregnancy. Some (10% to 20%) notice enlarged lymph nodes, mostly in the posterior cervical area, a sign that suggests relatively recently acquired infection. These enlarged nodes sometimes are still present at delivery. Clinical signs of infection in the pregnant woman are not necessarily associated with an increased predilection for transmission, as shown by the reports of cases in which, although the parasite was present in a lymph node biopsy performed as part of the diagnostic evaluation of lymphadenopathy, the offspring were uninfected [338,713,714]. Examples of similar cases of lymphadenopathy (with demonstration of the parasite in the nodes) in which congenital transmission did occur have been published [62,416,715,716].

Because a majority (greater than 80%) of cases of acquired *T. gondii* infection are subclinical, the diagnosis relies mainly on the results of serologic tests. To interpret serologic test results in the pregnant woman, it is important to understand how antibodies of different immunoglobulin classes and different specificities for antigenic determinants develop after the infection is acquired and which antibodies are detected in the different serologic methods used for diagnosis of this infection. In addition, the physician should have knowledge of the relationship of the time of acquisition of the infection to the onset of parasitemia (which results in infection of the placenta) and also to the onset of clinical manifestations (when present). The answers to many of these questions are unknown or only partly understood. What follows in this section is information and guidelines for interpretation of test results, as adopted from our personal experiences and supplemented by pertinent data from the literature. We have attempted whenever possible to distinguish between hypothesis and established fact.

**TABLE 31–24** General Considerations Regarding IgM, IgG, IgA, and IgE Antibody Responses to Postnatally Acquired Infection with *Toxoplasma*

| Antibodies | Uninfected Person | Recent (Acute) Infection | Chronic (Latent) Infection |
|---|---|---|---|
| ***IgM*** | | | |
| Directed toward antigens that cross-react | Present | Present | Present |
| Directed toward specific *Toxoplasma* antigens | Absent | Present in almost all cases. Period that IgM antibodies are present may vary from a few weeks to many months. Ability to detect these antibodies depends on serologic technique used. | Most often absent, but IgM antibodies may persist for years in some patients (about 5%). In such cases, titers are almost always low, but in some cases they remain high. Persistence of IgM antibodies is generally associated with low or medium titers of IgG antibodies. |
| ***IgG*** | | | |
| Directed toward antigens that cross-react | Absent | Absent (?) | Absent (?) |
| Directed toward specific *Toxoplasma* antigens | Absent (<2 IU/mL)* | Present. Rise from a low titer (2 IU/mL) to a high titer (300–6000 IU/mL). In a few patients, titers remain low (100–200 IU/mL). Duration of rise varies with patient and with serologic test used. Depending on serologic techniques, it may take from 2 to 6 mo for the IgG antibody titer to reach its peak. | Present. Stable or slowly decreasing titers (to a titer of 2–200 IU/mL). High titers (>300 IU/mL) persist for years in some patients (about 5%). A significant rise in titer is sometimes observed after a normal decrease in titer has occurred. |
| IgG avidity | Absent | Low | A high avidity test result reveals that the infection was acquired at least 12–16 weeks earlier. However, a low avidity test result may persist for more than 1 year. |
| ***IgA*** | | | |
| Directed toward antigens that cross-react | Absent | Absent (?) | Absent (?) |
| Directed toward specific *Toxoplasma* antigens | Absent | Present in almost all cases. Period that IgA antibodies are present may vary from several months to 1 year or more. They most commonly disappear by 7 months. | Most often absent |
| ***IgE*** | | | |
| Directed toward antigens that cross-react | Absent | Absent (?) | Absent (?) |
| Directed toward specific *Toxoplasma* antigens | Absent | Present | Absent |

**Titers are expressed in international units (IU) to minimize technical differences that might occur among different laboratories.*
IgA, IgE, IgG, IgM, *immunoglobulins A, E, G, M*; IU, *international units.*

The antigenic structure of *T. gondii* is complex; both cytoplasmic antigens, which are liberated when the organisms are lysed, and membrane antigens are involved in the immune response [717–723]. We know that certain antigens cross-react because normal human sera contain IgM antibodies that bind to these antigens [724–726]. It seems reasonable to suggest that antibodies formed in response to these different antigens differ both in their specificity and in their class and subclass of immunoglobulins [604]. These variations account for the fact that different antibodies may or may not be detected, depending on the serologic method employed.

In Table 31–24, we have attempted to describe the evolution of the IgM, IgG, IgA, and IgE antibody responses as they relate to interpretation of serologic test results in the diagnosis of *T. gondii* infection in the pregnant woman [610]. An example of the usefulness of these tests is shown in Table 31–25. The usefulness of the IgG avidity method is shown in Table 31–26 and discussed in an earlier section. Agreement between the avidity test and the HS/AC test is 97% in the Palo Alto laboratory, as discussed previously.

### Antibody Response in Relation to the Serologic Method Used

The methods for demonstration of specific IgM antibodies have been discussed earlier. They are valuable so long as it is possible to ascertain that a positive result is not due to the presence of “natural” IgM antibodies [727], rheumatoid factor, or antinuclear antibodies. For this reason, methods that rely on differences in titers after sera have been treated with 2-mercaptoethanol (e.g., the IHA and agglutination tests) are not satisfactory. Specific IgM antibodies may not be detectable within a few weeks after their first demonstration or may persist for years. In studies of women who seroconverted during gestation, IgA antibodies as measured by ELISA appeared at

approximately the same time as for IgM antibodies [642]. Similar results have been observed with the IgE ISAGA [614,728]. Antibody titers in the IgE ISAGA decrease more rapidly than do IgA antibodies. In the study by Pinon and coworkers [614], they persisted for less than 4 months in 23 patients tested serially. In the study by Wong and associates, the IgE ISAGA results were similar to those reported by Pinon and coworkers, whereas IgE antibodies measured by ELISA persisted significantly longer in some seroconverters [639].

Titers in the dye test, the agglutination test, and the IHA test (when these latter two tests are performed with 2-mercaptoethanol) depend on the concentration of IgG antibodies; this is true also for the conventional IFA test when performed with a conjugate specific for IgG. Nevertheless, depending on which test is used, differences in the rise and fall of IgG antibody titers are noted; titers in the dye test rise more rapidly, whereas those measured in the agglutination and IHA tests in the presence of 2-mercaptoethanol rise slowly.

A summary of the IgG antibody responses to *T. gondii* infection, as measured by different serologic methods, is given in Table 31–27. For a discussion of the IgG avidity method, see earlier under "Demonstration of Antibodies in Serum and Body Fluids."

A special comment regarding the agglutination test is made here because of its commercial availability and increasing usefulness for screening and diagnosis of the acute infection in pregnant women. With the whole-cell agglutination test, agreement with the dye test was virtually 100%, except in some patients tested within a few days after they became infected, when only IgM antibodies were present [619]. With these serum samples, the dye test result was at times positive while the agglutination test result was still negative. By contrast, the agglutination test result may be positive at times when the dye test result is negative in chronically infected persons. This is due to the greater sensitivity of the agglutination test for detection of low titers of IgG antibodies. Because it takes more than 2 months (2 to 6 months) for IgG

**TABLE 31–27** IgG Antibody Responses to *Toxoplasma* Infection as Measured by Different Serologic Methods*

| Serologic Method | Uninfected Person | Recent (Acute) Infection | Chronic (Latent) Infection |
|---|---|---|---|
| Dye test | Negative (<1:4) | Rising from a negative or low titer (1:4) to a high titer (1:256 to 1:128,000). | Stable or slowly decreasing titer. Titers usually are low (1:4 to 1:256) but may remain high (≥1:1024) for years. |
| Agglutination test (after treatment of sera with 2-mercaptoethanol) | Negative (<1:4) | Rising slowly from a negative or low titer (1:4) to a high titer (1:512). If a high-sensitivity antigen is used, the titer may reach 1:128,000. | Stable or slowly decreasing titer. Titers usually are higher than in the dye test if a high-sensitivity antigen is used. Striking differences between dye test and agglutination test titers are observed in some patients. |
| IHA test (after treatment of sera with 2-mercaptoethanol) | Negative (<1:16) | Rising very slowly from a negative or low titer (1:16) to a high titer (1:1024). It may take 6 mo before a high titer is reached; in some patients, high titers are never observed | Stable or slowly decreasing titer. Titers usually are higher than in the dye test if a high-sensitivity antigen is used. Striking differences between dye test and agglutination test titers are observed in some patients. |
| Conventional IFA test (conjugated antiserum to IgG) | Negative (<1:20) | Rise in titer is parallel to rise in dye test titer, but decrease in titer might be slower than that in dye test. | Stable or slowly decreasing high or low titer. |

antibodies detected with the whole-cell agglutination test to reach a steady high titer, the existence of a steady high titer signifies that the infection was acquired more than 2 months earlier. As a consequence, if the first sample of serum has been obtained during the first 2 months of pregnancy, a stable agglutination test titer demonstrates that the infection occurred before the time of conception and that the risk of congenital infection in the infant is low [619].

It is exceedingly difficult to establish guidelines for interpretation of serologic methods that measure both IgM and IgG antibodies. For example, in examining paired sera that were stated to have high stable titers in the conventional IFA test (performed with a conjugate against total immunoglobulins), we frequently have observed a definite rise in titer between the samples when a method specific for IgG antibody was used (e.g., the dye test or the agglutination test performed with 2-mercaptoethanol). Although both samples had the same titer in the conventional IFA test, the titer in the first sample was the sum of the anti-IgM and anti-IgG antibody activities of the conjugate, whereas the titer in the second sample reflected only the anti-IgG antibody activity of the conjugate.

Establishing guidelines for the IHA and CF tests is made difficult by the fact that different antigen preparations cause markedly different results: Some preparations detect IgM antibodies, some detect IgG antibodies, and others detect both. Thus the evolution of the antibody response may differ not only when different tests are used but also when the same test is used in different laboratories. This problem has been paramount in the confusion surrounding the subject of the practical approach to diagnosing acute infection.

In a systematic screening program (Desmonts G and Thulliez P, unpublished data) in which follow-up sera from pregnant women are examined monthly, IgM antibodies are usually the first to appear, but low titers of IgG antibodies, as measured in the dye test, also appear early. Sera in which only IgM antibodies are detectable are uncommon. A rise in IgM antibody titer is infrequently observed, suggesting that the IgM antibody titer rise is steep and that this rise does not last longer than 1 or 2 weeks before reaching its peak. By contrast, the rise in IgG antibody titer initially is slow. The titer, as measured in the dye test, usually remains relatively low (2 to 100 IU/mL or 1:10 to 1:100) for 3 to 6 weeks. Recognition of this fact is critical for proper interpretation of serologic test results when serum samples obtained 2 to 3 weeks apart are tested in parallel, especially if the dye test is performed with fourfold dilutions of the sera, which would require an eightfold (two-tube) rise in titer to be considered significant. In testing such sera in parallel, it is imperative to use twofold dilutions so that a fourfold (two-tube) rise can be detected. In our experience, this rise is difficult to detect in the IgG IFA test. After the initial 3 to 6 weeks, the rise in IgG antibody titer becomes steeper; high titers (greater than 400 IU/mL or 1:1000) usually are reached within an additional 3 weeks. Thereafter, the rise in titer is slower but may still be detectable over an additional 3 to 6 weeks if careful quantitative methodology is used (here again, this rise will be missed if fourfold dilutions of sera are used). Thus although the rise in IgG antibody titer as detected in the dye test differs from one case to another, it lasts for more than 2 months and sometimes as long as 3 months. The rise in IgG antibody titer, as detected in the agglutination test (in the presence of 2-mercaptoethanol), may parallel exactly the pattern described for the dye test, or the titer may rise more slowly; the peak may not occur earlier than 6 months after infection. As mentioned previously, by 6 months, titers in the IgM IFA test are no longer demonstrable in most cases. Titers in the capture IgM ELISA and in the IgM ISAGA, however, usually remain positive for this period, and in women who acquire the infection during pregnancy, the titers in these latter two tests are almost always positive at the time of parturition (the level of the titer depends on the duration of infection before delivery).

Although definitive data are not available, when specific treatment for *T. gondii* infection is administered early during the initial antibody response (when the IgG antibody titer is still low), it appears that the antibody response may be slowed and the titer (e.g., in the dye test, conventional IFA test, or ELISA) may remain relatively low so long as treatment is continued. A late (delayed) rise often is observed after cessation of treatment.

### Practical Guidelines for Diagnosis of Infection in the Pregnant Woman

Guidelines for diagnosis of *Toxoplasma* infection are presented for three clinical scenarios: (1) that of a woman pregnant for a few weeks in whom a serologic test for *T. gondii* infection was performed on a routine basis by her physician or at her request; (2) that of a woman pregnant for a few months who is suspected of having acute toxoplasmosis; and (3) that of a woman who has just given birth to an infant suspected of having congenital toxoplasmosis. In almost all cases in the United States, the diagnosis in these situations must take into consideration two pieces of data: the results of a test for IgG antibodies (e.g., dye test, ELISA, IFA) and the results of a test for IgM antibody (e.g., IgM IFA, IgM ISAGA, or IgM ELISA). The accuracy of some ELISA kits being sold at present is unsatisfactory, and proper interpretation of the results of titers obtained for many of these kits has not been defined clearly. A number of studies attest to problem of false-positive and false-negative results obtained with certain kits that employ IFA or ELISA technology.*

Clinical Scenario 1: Very Early Pregnancy (first few weeks). If no antibody is demonstrable, the patient has not been infected and must be considered at risk of infection. A positive IgG test titer and a negative test result for IgM antibodies or high-avidity antibody test can be interpreted as reflecting infection that occurred months or years before the pregnancy, although very rarely IgM *T. gondii* antibodies may not be detected in recent infections. Essentially, there is no risk of the patient's giving birth to a congenitally infected child (unless she is immunosuppressed), regardless of the level of antibody titer. No matter how high the titer is, it should not be considered prognostically meaningful.

If IgM antibodies are present, the avidity test should be performed. If this is unavailable, the IgG test should be performed, with results compared with those for a second sample taken 3 weeks after the first. If no rise in IgG antibody test titer occurs, the infection was acquired before pregnancy, and almost no risk to the fetus exists. If a rise in IgG antibody test titer is observed, the infection probably was acquired less than 2 months previously, perhaps around the time of conception. In this situation, the risk of giving birth to an infected child is very low (see Table 31–8).

Clinical Scenario 2: Early Pregnancy (within a Few Months) plus Suspected Acute Infection. The diagnosis depends on three criteria: (1) the presence of lymphadenopathy in areas compatible with the diagnosis of acute acquired toxoplasmosis [346,538,539,592,731–742], (2) a high IgG test titer (300 IU/mL or greater), and (3) presence of IgM antibody. If two of the three criteria are present, for purposes of management, the diagnosis of acute acquired toxoplasmosis should be considered likely. If, however, the IgG test titer is less than 300 IU/mL, a significant rise in titer should be demonstrable in a second serum sample obtained 2 to 3 weeks later. The avidity assay is particularly helpful in this setting. A high-avidity test result indicates acquisition of infection more than 12 to 16 weeks earlier (see earlier under "IgG Avidity Assay").

Important to consider in the pregnant patient in whom lymphadenopathy is observed is that high-avidity results were demonstrable only in those women whose lymphadenopathy had developed at least 4 months earlier [90]. Therefore, a high-avidity test result in a pregnant woman with recent development of lymphadenopathy (e.g., within 2 or 3 months of performing the avidity test) suggests a cause other than toxoplasmosis, and further workup is warranted to determine the cause of the lymphadenopathy. In that same study of the IgG avidity test in patients with lymphadenopathy, low-IgG avidity antibodies were observed in sera of patients whose lymphadenopathy had developed as long as 17 months before the time of serum sampling for testing. (This provides additional proof that low-IgG avidity test results should not be relied on for diagnosis of recently acquired infection.)

Clinical Scenario 3: Suspected Congenital Toxoplasmosis in a Newborn Infant. The diagnosis of the acute acquired infection in women who have just given birth to a child with suspected congenital toxoplasmosis is rarely difficult. As a rule, diagnosis of recent infection in the mother relies on the IgG test titer and the results of tests for IgM antibodies. Paradoxically, examination of maternal sera frequently is more useful for diagnosing subclinical or atypical congenital toxoplasmosis in a neonate than is examination of the child's serum. If IgM antibody is detected in the mother and no prior serologic test results are available, her newborn should be examined clinically and serologically to rule out congenital infection.

Because IgM antibodies as measured by ELISA or ISAGA may persist for many months or even years, their greatest value is in determining that a pregnant woman examined early in gestation has not recently been infected. A negative result virtually rules out recently acquired infection unless sera are tested late in gestation (in which case IgM antibodies may no longer be detectable), or so early after the acute infection that an antibody response has not yet occurred (in which case the acute infection would be identified in a screening program in which follow-up serologic testing is performed in seronegative pregnant women). A positive IgM test result is more difficult to evaluate, unless a significant rise in IgG or IgM titer can be demonstrated when sera are tested in parallel or when results of other tests (e.g., tests for IgA and IgE antibody and the HS/AC test) suggest recent infection. A very high IgM, IgA, or IgE titer is more likely to reflect recent infection, although such high titers may persist for months. Such positive sera should be confirmed with additional methods, such as the HS/AC or avidity test. In most cases, use of and consultation with a reference laboratory will be required. In the Palo Alto laboratory, a "chronic" pattern in the HS/AC test agrees virtually 100% with a "chronic" titer in the IgG avidity test.

*References 590, 652, 653, 712, 729, 730.

In the unusual situation in which a pregnant woman has a positive IgM antibody titer and a persistently negative IgG titer, a false-positive IgM result must be considered, and if feasible, all such patients should have IgG antibodies measured by a different method [57,733,734]. Examples of the serologic response in women who seroconverted during pregnancy are shown in Table 31–25.

Pinon and colleagues in France fortuitously diagnosed two cases of congenital toxoplasmosis in newborns whose mothers did not have detectable *T. gondii* antibodies at the time of birth. These cases prompted the investigators to perform a study over an 18-month period to determine by postnatal serologic follow-up whether they could detect women who were infected but whose results of serologic testing were negative at the time of delivery. They detected four cases of perinatal maternal infection, and two of these resulted in infected offspring. In view of these results, and to prevent missing maternal infection at the end of pregnancy, they suggest that serologic testing of seronegative women who have been screened monthly should continue such that the last blood sample is obtained approximately 30 days after they have given birth [57].

## Prenatal Diagnosis of Fetal *Toxoplasma* Infection

Although PCR assay in amniotic fluid is now the method of choice, cordocentesis [735–737] may still be used when PCR methods are unavailable or in the rare instances in which the PCR assay result is negative and the ultrasonographic findings suggest fetal infection. For this reason, findings on clinical studies using this method are described here along with those for PCR analysis.

### *Amniocentesis: Polymerase Chain Reaction Assay in Amniotic Fluid*

Results of PCR analysis performed in different laboratories may differ considerably; a result reported as positive or negative from one laboratory may even be the opposite of that from another laboratory. At present, no procedures for quality control in laboratories performing PCR assay for prenatal diagnosis are in place. PCR assay results from any laboratory must be reviewed with caution, and if possible, information or data on the reliability and validation data of the PCR tests from that laboratory should be requested.

In 1994, Hohlfeld and coworkers from Paris [77] published a follow-up to their cordocentesis study reported in 1988 [82]. Prenatal diagnosis, which included amniocentesis, ultrasonography, and fetal blood sampling, was performed in 2632 women who had acquired *T. gondii* infection during gestation. One hundred ninety-four cases of congenital toxoplasmosis were identified, and 178 of these were diagnosed by conventional methods of prenatal diagnosis. No false-positive results were reported. The overall sensitivity was 92%, the specificity was 100%, and the negative predictive value was 99%. The sensitivity of the IgM antibody test was 28%; of mouse inoculation with fetal blood, 72%; of mouse inoculation with amniotic fluid, 64%; and of tissue culture of amniotic fluid, 64%. The overall rate of spontaneous fetal loss was 1.3%. PCR assay was performed in the amniotic fluid in 339 consecutive women, and the results were compared with those obtained by the conventional methods. By conventional testing, congenital infection was demonstrated in 34 fetuses, and in each the PCR test result also was positive. In three additional fetuses, only the PCR assay result was positive, and in each, the diagnosis of congenital infection was confirmed on follow-up investigation (autopsy in two and serologic study in one). One false-negative result was obtained with the PCR assay, and no false-positive results. The investigators concluded that the PCR assay is a more reliable, safer, simpler, and less expensive method than the conventional methods they had been using, and that it can be used from week 18 of gestation until term. They also concluded that fetal blood sampling is no longer necessary, and that amniocentesis together with the PCR test and inoculation of mice (tissue culture is less sensitive) is preferred (Table 31–28). The authors did not have data on the efficacy of testing amniotic fluid before 18 weeks of gestation. They stated that prenatal diagnosis should not be attempted until at least 4 weeks after the acute infection in the mother.

In 1998, Jenum and associates published the Norwegian experience with a nested PCR technique using amniotic fluid collected from 67 women diagnosed as having acquired the infection during gestation [590]. They also used mouse inoculation on each of the samples. They commented on the greater sensitivity of the PCR method because mouse inoculation results were affected by treatment in the mothers. Whereas Hohlfeld and coworkers [77] found a specificity of 100%, Jenum and associates [82] observed a specificity of only 94%, despite careful technical steps to avoid contamination of their samples. Their reported positive predictive value was 67%, with 10 true positives among 15 positive results. Three of eight infants with congenital toxoplasmosis diagnosed after birth had a negative result on PCR assay and mouse inoculation on prenatal examination. Thus in their study, a positive PCR assay result did not confirm infection in the fetus. For this reason, the researchers stated that

**TABLE 31–28** Diagnostic Value of the Polymerase Chain Reaction (PCR) Assay Compared with Conventional Methods for Prenatal Diagnosis of Congenital *Toxoplasma gondii* Infection in 339 Pregnancies

| Variable | PCR* | Conventional Methods*,† |
|---|---|---|
| Sensitivity | 37/38 (97.4; 86.1–99.9) | 34/38 (89.5; 72.2–97.0)‡ |

positive results also require serologic follow-up testing for confirmation of the diagnosis. Prenatal diagnosis using PCR assay performed in amniotic fluid from each twin in a dizygotic pregnancy was recently reported by Tjalma and colleagues [740].

Because physicians must make decisions regarding management of a pregnancy after results of amniocentesis are obtained, it is of utmost importance that the PCR assay be specific insofar as there are no false-positive results. For example, according to a recent report, the use of a nested PCR technique [590] did not appear to yield results that fit this requirement; therefore, that nested PCR method cannot be considered to represent an improvement over conventional methods for prenatal diagnosis.

One shortcoming of the study reported by Hohlfeld and coworkers [77] is that the sensitivity and negative predictive value of the PCR assay in amniotic fluid were compared with those of conventional methods but were not analyzed relative to the status of the infection in the liveborn infants. The enthusiasm that has been generated for the reliability of the PCR assay should be tempered by the fact that because of the delay that can occur between the time of maternal infection and transmission of the parasite to the fetus (transmission may occur after the date of the amniocentesis), all congenital infections are not and cannot be identified by prenatal diagnosis. One case that suggests such a delay is reported in the publication by Hohlfeld and coworkers [76]. Before PCR testing was used for prenatal diagnosis, it was well recognized that not all cases of congenital *T. gondii* infection could be detected prenatally. Of 89 congenital infections, Hohlfeld and coworkers [77] reported 9 cases (10%) with a negative result on prenatal diagnostic testing. In other published series, the rate of congenital infections with no prenatally identified abnormal findings varied, ranging from 3% in the study by Pratlong and coworkers [741] to 8% in that by Berrebi and associates [742]. Actually, the number of infections that were not detected by the prenatal diagnostic procedures was underestimated in each of these studies, because a significant number of the offspring were lost to follow-up (50 of 211 [24%] [741]), or data were not provided by the investigators [77]. Before the use of PCR methods, it was not possible to define whether these discrepancies were due to a lack of sensitivity of the diagnostic procedures or to the fact that transmission of the parasite occurred after the amniocentesis or cordocentesis was performed. The higher sensitivity of PCR assay when compared with conventional methods explains why congenital infection had been missed in the past when the less sensitive conventional methods were used.

Nonetheless, a negative PCR test result in amniotic fluid does not rule out infection in the fetus.

In France, Kieffer and colleagues (2009) estimated the sensitivity, specificity, and positive and negative predictive values, per trimester and over all of pregnancy, for detection of *T. gondii* in amniotic fluid using real-time PCR. The cohort included 377 pregnant women identified as having *Toxoplasma* infection through prenatal screening. Available data included gestational age of maternal infection, details of maternal treatment, amniocentesis results, neonatal work-up and definitive infection status of the child. PCR analysis occurred in 261 (69%) of 377 patients. Except for 4 negative results for children who were infected, PCRs were accurate. Overall sensitivity was 92.2% (95% CI 87-98%) and the negative predictive value was 98.1% (95% CI 95-99%). Specificity and positive predictive values were 100%. A significant association did not occur with the trimester of maternal acquisition of infection. Thus, Real-time PCR for the 300 copy, 529 base pair *T. gondii* gene improves detection of *T. gondii* in amniotic fluid and is useful for determining whether there is fetal infection and for consequent proper treatment and monitoring. Neonatal evaluations are still necessary to determine manifestations of infection and for those who had negative PCR, to help to more definitively exclude infection.

In a study performed to determine whether quantification of PCR results would be helpful in predicting outcome of the infection in the fetus or newborn, parasite concentrations were estimated by real-time quantitative PCR assay in 88 consecutive positive amniotic fluid samples from 86 pregnant women [206]. Results were analyzed according to the gestational age at maternal infection and the clinical status in fetuses during pregnancy and at birth. A significant negative linear regression was observed between gestational age at maternal infection and parasite loads in amniotic fluid (see Fig. 31–20).

After adjustment for gestational age at maternal seroconversion, parasite concentration in amniotic fluid, and the total duration of prenatal treatment in the multivariate analysis, the two variables significantly and independently associated with most severe signs of infection (fetal death or cerebral ventricular dilation) were an early gestational age at maternal infection (odds ratio = 1.44/decreasing week gestation [95% CI, 1.12% to 1.85%]) and high parasite amniotic fluid concentrations (odds ratio = 15.4/log [parasites/mL of amniotic fluid] [95% CI, 2.45% to 97.7%]). In this series, each of the 11 cases in which parasite loads were greater than 100/mL, with onset of infection before 20 weeks, resulted in severe impairments in the offspring, indicating a 100% predictive value of poor prognosis (see Fig. 31–20).

The earlier in gestation infection occurs, the higher the parasite burden. Parasite burden in amniotic fluid as determined by quantitative PCR analysis also is a prenatal biologic marker of the severity of congenital infection. In a dizygotic twin pair, one had no parasites, and the other had greater than 600 parasites per milliliter. At pregnancy termination, the former infant had no signs of infection; the latter had disseminated multivisceral infection. Members of a second twin pair—one with clinical signs and the other without such signs—similarly were dicordant for parasite burden in amniotic fluid (3.2 versus 2800 parasites per milliliter), and both died. The twin with hydrocephalus and ventriculomegaly probably was the twin with amniotic fluid with the higher parasite burden (2800 parasites per milliliter).

Ultrasound examinations (Figure 31-26) are still required and should be performed each month following a negative PCR result on amniocentesis because congenital infections with extensive involvement and hydrocephalus have occurred in the setting of a negative PCR assay result. When the ultrasound appearance remains normal, it is still necessary to continue clinical and serologic follow-up

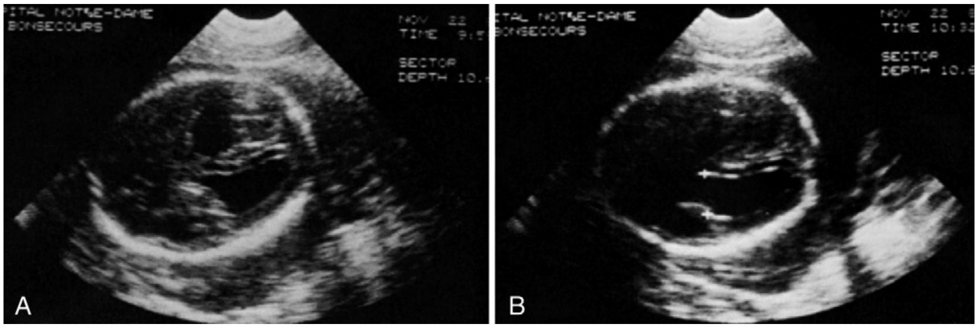

**FIGURE 31–26** **A** and **B**, Ultrasound study of fetus with hydrocephalus resulting from toxoplasmosis. *(Courtesy of F Daffos, Paris.)*

evaluation of infants until congenital infection is definitively ruled out.

### Immunoglobulin A Antibodies

The value of demonstration of IgA *T. gondii* antibodies in the fetus is now well recognized [642,647,741,743,744]. Therefore, testing for these antibodies for this purpose should be routine in all laboratories that test newborns for suspected congenital *T. gondii* infection.

### Interferon

Interferon has been demonstrated in blood of fetuses infected with *T. gondii*, suggesting that the fetus is able to synthesize this cytokine as early as 26 weeks of gestation [745]. Its demonstration appears helpful when interferon level determination is used with other nonspecific tests for diagnosing *T. gondii* infection in the fetus. Interferon serum levels that were significantly higher than in controls also were demonstrated in sera of pregnant women during seroconversion for *T. gondii* antibodies [745].

### T-Cell Subsets

T-cell subsets were evaluated in a group of uninfected and infected fetuses [746]. Significant differences from controls were noted in that the infected fetuses were characterized by a smaller percentage of $CD3^+$ and $CD4^+$ T cells and a decrease in absolute number of $CD4^+$ cells and lower $CD4^+/CD8^+$ ratio. The mothers in this study were receiving treatment, and the possible results of this treatment on T cells could not be excluded. In addition, because the number of infected fetuses was small, it was not possible to analyze the values obtained relative to gestational age, as was done in the control, uninfected fetuses.

In another study, Lecolier and coworkers studied T lymphocyte subpopulations in normal and in six *T. gondii*-infected fetuses [743]. They noted a significant increase in number of $CD8^+$ T cells in two cases investigated soon after maternal infection (3 and 6 weeks, respectively) and a significant decrease in number of $CD4^+$ T cells in the four other cases that were investigated later (7 to 13 weeks after maternal infection). These observations suggest that alterations in T lymphocyte subsets in the infected fetus are similar to those that occur in the acute acquired infection in adults [257]. In another study by Foulon and associates, these results were not confirmed [551,550]. Thus further study is necessary to evaluate whether study of T-cell subsets will be a useful adjunct in prenatal diagnosis.

### Complement

It appears that the C4 component of complement is significantly increased in fetuses congenitally infected with *T. gondii*. Gestational age is important in interpretation of results, but the measurement of C4 levels in the fetus may be a useful nonspecific adjunctive test for prenatal diagnosis [747].

## Serologic Diagnosis in the Newborn

Because of the pleomorphism of congenital toxoplasmosis, because the infection most often is subclinical in the newborn, and because the infection may be mimicked by other infections and diseases of the neonate, the diagnosis of congenital *T. gondii* infection is far more complicated than is diagnosis of the acquired infection.

The serologic diagnosis of congenital *T. gondii* infection in the newborn is particularly difficult because of the high prevalence of antibodies to *T. gondii* among normal women of childbearing age in the United States and in much of the rest of the world. Thus a high antibody titer in a newborn may merely reflect past or recent infection in the mother (maternal IgG antibody having passed transplacentally to her fetus).

The fact that infection in the fetus may stimulate production of sufficient IgM to result in abnormally high levels of this immunoglobulin in the newborn has been shown in a variety of congenital infections by Stiehm and associates [690] and by Alford and coworkers [748,749]. Thus quantification of IgM in cord serum may be a valuable screening device for detecting infection in the newborn. At present, the consensus of those working on immunologic responses to perinatal infection is that enough "false-negative" results occur to suggest that quantification of IgM in the newborn may not be universally applicable for diagnosing infection [255,750,751]. Such false-negative results are not infrequent in premature infants with proven rubella [255]. For a nonspecific test to be beneficial as a screen, it seems that a slight excess in sensitivity resulting in overdiagnosis (false-positive results) can be accepted, but that lack of sensitivity in known cases, resulting in underdiagnosis (false-negative results) cannot be accepted.

As mentioned earlier, demonstration of IgM, IgA, or IgE antibodies to *T. gondii* in serum of the newborn is diagnostic of congenital *T. gondii* infection if contamination with maternal blood has not occurred. When an appropriate fluorescein-tagged antiserum to IgM has been

employed, we have not had any false-positive results except for the qualifications mentioned earlier for the IgM IFA method. Because high levels of maternal IgG antibodies to *T. gondii* may compete for antigenic sites on the surface of the organisms [686] with the relatively low IgM antibody levels usually found in the fetus or neonate, weak reactions and low IgM antibody titers (1:2) indicate infection in the newborn. Even allowing for these weakly positive reactions, however, detectable specific IgM antibody is absent in the sera of most neonates with congenital toxoplasmosis (approximately 75%) when the IgM IFA test is used [480]. This false-negative result rate was only approximately 20% if the double-sandwich IgM ELISA method was used [608]. Because of the high incidence of false-negative results for the IgM IFA test, we recommend that the capture IgM ELISA or ISAGA method be used instead. It is noteworthy that the proportion of infants showing IgM antibody is the same whether illness is clinically manifest or subclinical. IgA antibodies have been demonstrated in as high as 90% of newborns with the congenital infection [642,752], which further attests to the great value of testing for these antibodies (Table 31–29). A number of investigators have reported greater sensitivity of IgA antibody determination for diagnosis in infected children than for IgM [611,641,642,753,754]. As emphasized by Foudrinier and coworkers, specificity of IgA detected at birth must be confirmed because equivocal and positive IgA test results were found in newborns during the first days of life, whereas subsequent sera became negative within less than 10 days [754]. They concluded that in a neonate born to a mother with IgA or IgM *T. gondii* antibodies, a positive IgA or IgM test result must be interpreted with caution and be confirmed after approximately 10 days of life, unless the diagnosis is established before this time. Additional data are needed to clarify whether all newborns with a positive IgA or IgM antibody titer at approximately 10 days of age are indeed infected, especially in those cases in which the maternal IgA or IgM antibody titers were very high. Determination of levels of β-human chorionic gonadotropin and of total IgA may prove to be of value as adjunctive tests.

**TABLE 31–29** Serologic Test Results for IgM and IgA Antibodies at Birth and During the Newborn Period in Sera of 23 Congenitally Infected and 49 Uninfected Offspring of Mothers Infected During Gestation*

| Trimester Mother Acquired Infection (Time Test Performed) | IgM– IgA– | IgM+ IgA+ | IgM+ IgA– | IgM– IgA+ |
|---|---|---|---|---|
| Uninfected (at birth) | 47 | 0 | 1 | 1 |
| Infected (at birth) | | | | |
| 1st trimester | 1 | 1 | 0 | 2 |
| 2nd trimester | 1 | 0 | 0 | 5 |
| 3rd trimester | 2 | 8 | 1 | 0 |
| Infected (follow-up 1 wk to 3 mo) | 3 | 11 | 0 | 9 |

Of note, however, we have never observed a false-positive result after the first day of life when the ISAGA was used for detection of IgM antibodies.

The value of demonstration of IgE antibodies also is clear. In one of our laboratories (Remington JS), 19 of 21 infants (90%) (ages birth to 5 weeks) with congenital toxoplasmosis and signs of CNS involvement tested positive for IgE antibodies (92% by ELISA and 62% by ISAGA) [639]; of the 10 tested in the first week of life, 9 had IgM antibody, and all 7 of those tested for IgA antibodies were seropositive. Seven of the 21 were first tested in the second week of life; 6 had IgM antibodies, and all 5 of those tested for IgA were seropositive. Of the 4 first tested at 3 to 5 weeks of life, 3 had both IgM and IgA antibody; 1 infant had neither [639]. In studies by Pinon and colleagues, 52 cases of congenital *T. gondii* infection (5 symptomatic and 47 "asymptomatic" cases) were studied; at birth or during the first month of life, none of the symptomatic and 13 (25%) of the "asymptomatic" infants were seropositive by IgE ISAGA. Thirty-five of the 52 infants (67%) were seropositive for IgA antibody by ISAGA [755,756].

If the infant is infected in utero at a time when it is immunologically competent to produce IgM antibodies but before the passage of maternal IgG *T. gondii* antibodies across the placenta has occurred, there is no reason to suspect competition for recognition of antigenic sites on the parasite. Data derived from studies of infants with very high IgM titers in the early newborn period support this hypothesis. Table 31–30 displays clinical and serologic data representing such an instance in a mother and her infant. The mother had had a high but stable dye test titer since the ninth week of pregnancy and a negative IgM IFA test titer. The same results were obtained during week 13. This finding suggests that infection occurred at about the time of conception or a few weeks earlier. She did not receive treatment and gave birth to a severely infected infant with generalized toxoplasmosis who died 8 days after delivery. This newborn had an unusually high IgM test titer. If, however, high titers of maternal antibody are present in the fetus before the organism reaches the fetus, as a consequence of delay by the placental barrier discussed earlier, it is possible that IgG antibody might compete (and "cover") for recognition sites [686] on the parasite or may by other means (e.g., feedback mechanism) suppress fetal IgM antibody synthesis. (This also might explain the paradoxical occurrence of an elevated IgM level in the serum of an infected infant in the presence of a negative IgM test titer.) That this may occur has been shown in an experimental animal model [757]. In our experience, IgM antibody titers usually decrease rapidly after the infant's own IgG antibodies have reached a high titer; at 1 year of age, IgM antibodies usually are not demonstrable or are present in very low titer.

In the absence of demonstration of the parasite, IgM or IgA antibodies to *T. gondii*, follow-up testing of infants with suspected toxoplasmosis is the only means of making a serologic diagnosis of subclinical toxoplasmosis. For proper interpretation of test titers in infants who are past the immediate newborn period, it is important to understand how passively transmitted maternal IgG decreases in the uninfected infant. Because the literature is replete

**TABLE 31–30** Data in a Mother Who Acquired *Toxoplasma gondii* Infection at About the Time of Conception or a Few Weeks Earlier Who Had a Negative IgM Test Titer and Whose Infant Had a High IgM Test Titer

| Subject | Stage of Pregnancy or Age | Clinical Manifestations | Titer | | *T. gondii* Isolated |
|---|---|---|---|---|---|
| | | | *Dye Test* (IU/mL)* | *IgM Test†* | |

with misinformation on the interpretation of *T. gondii* serologic studies in older infants, this important subject is dealt with here. In Figure 31–27, curve 1 shows the total serum IgG values in milligrams per deciliter in the newborn and infant to the age of 1 year. The values in the newborn at birth frequently are somewhat higher than they are in the mother and subsequently decrease. Minimal values (e.g., 300 to 400 mg/dL) are observed at about the third or fourth month, after which time the level increases with increasing production of IgG by the infant. Maternally transmitted antibodies (curve 2) progressively disappear because they are not synthesized by the infant. Their half-life is approximately 30 days; that is, they decrease by approximately one half per month (Fig. 31–28).

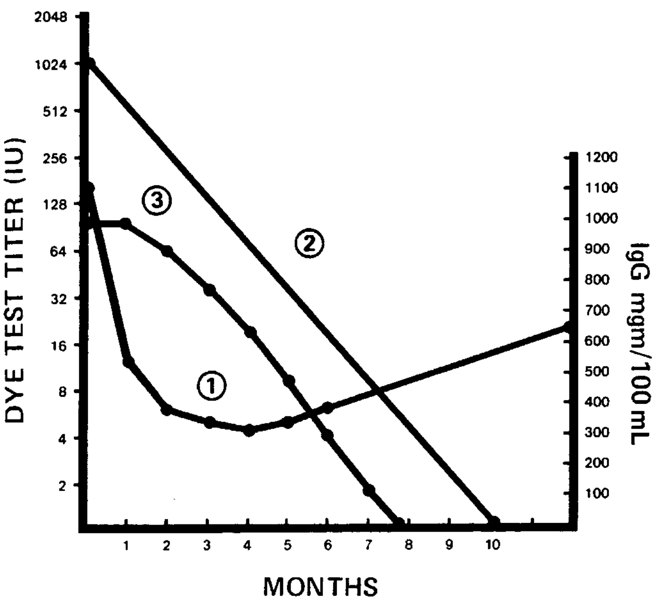

**FIGURE 31–27** IgG and *Toxoplasma* antibodies: uninfected child. Curve 1, mg of IgG/dL; curve 2, IU of *Toxoplasma* antibody per ml; curve 3, IU of *Toxoplasma* antibody per mg of IgG. *(Data from Desmonts G, Couvreur J. Toxoplasmosis: epidemiologic and serologic aspects of perinatal infection.* In *Krugman S, Gershon AA [eds]. Infections of the Fetus and the Newborn Infant. Progress in Clinical and Biological Research, vol 3. New York, Alan R Liss, 1975.)*

Figure 31–29 shows actual data from an uninfected infant plotted against the background of the theoretical decay curve for IgG maternal antibody (approximately one half the value every 30 days). Thus a titer of 1000 IU/mL at birth should drop to 1 IU/mL in 300

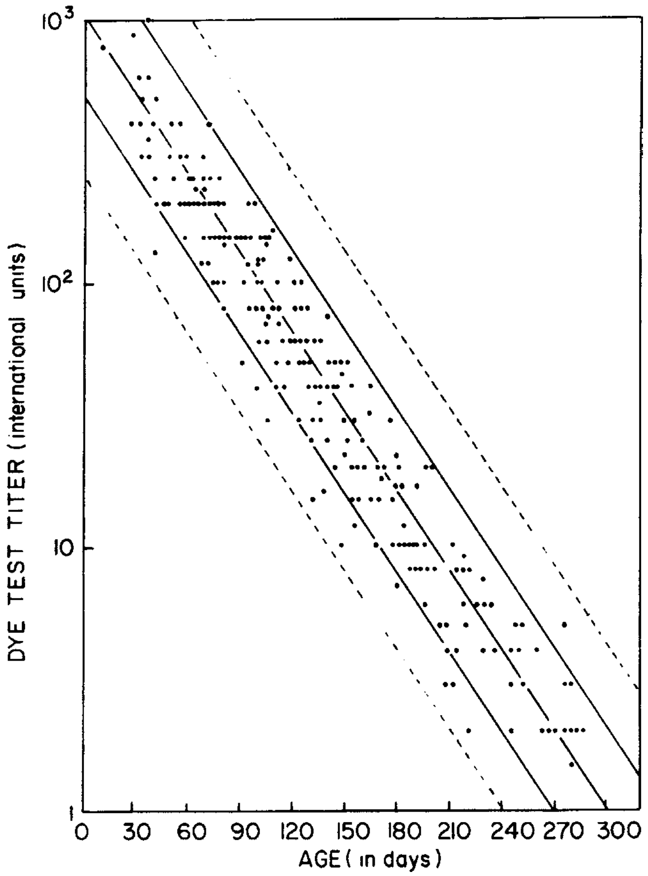

**FIGURE 31–28** Decrease in maternally transmitted *Toxoplasma* antibodies (dye test) in uninfected infants. The two parallel lines indicate one-half and twice the titer, plus or minus one twofold dilution. The result in one serum sample of each pair is on the theoretical line and is not represented by a dot. The result in the other serum sample of each pair is represented by a dot.

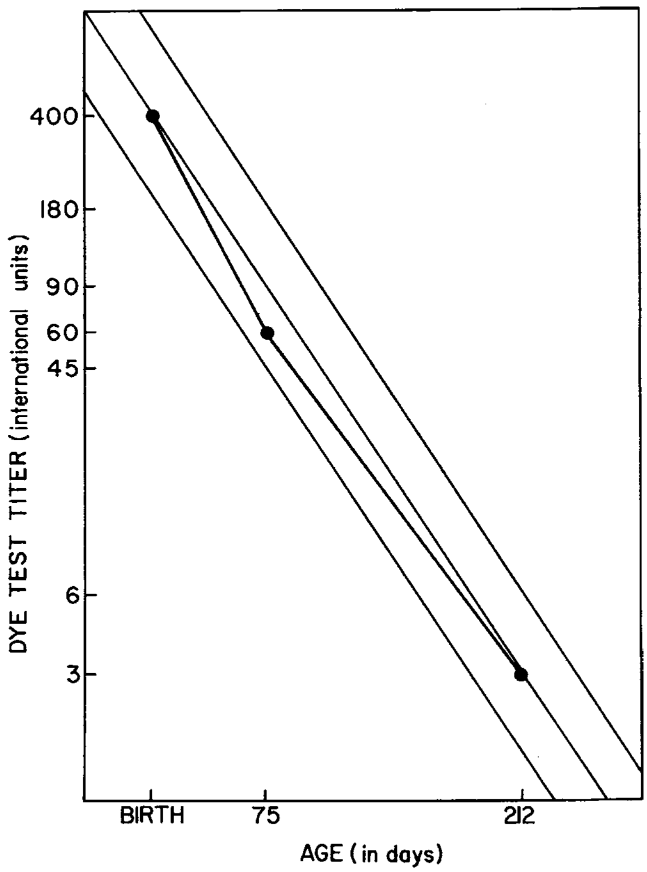

**FIGURE 31–29** Evolution of maternally transmitted antibody (dye test) in an uninfected infant from birth to the age of 212 days.

days. The infant whose titers are shown here had titers of 400 IU/mL at birth, 60 IU/mL at 75 days, and 3 IU/mL at 212 days. These are exactly the expected values. Figure 31–28 shows results obtained in 430 paired sera from 93 uninfected infants with passively transmitted maternal antibodies plotted against their theoretical values. Ninety-three percent of the actual titers are less than onefold to twofold dilution different from the expected values. These data preclude acceptance that all infants with a positive titer at 4 to 6 months have congenital toxoplasmosis. The same rate of decrease applies to both high and low titers. It takes approximately the same amount of time for a decrease from 1000 to 250 IU/mL, a seemingly very significant variation, as for a decrease from 4 to 1 IU/mL, a titer difference that most investigators would consider negligible (i.e., no significant difference).

For a better estimate of this decrease in passively transmitted maternal antibodies, it is useful to compare the antibody titer and the level of IgG and to compute the specific antibody load (i.e., the ratio of specific antibodies [number of IU/mL] to total IgG). This is represented diagrammatically in Figure 31–27 by curve 3 and in Table 31–30. In Figure 31–27, as late as the fourth to sixth week of life, usually no change in the antibody load is observed; the IgG is still mainly maternal in origin. Although the titer of antibodies decreases, the total IgG decreases in a similar manner. As a result, the ratio remains constant. During the second and third months, the amount of IgG synthesized by the infant increases. Because this newly synthesized IgG does not contain antibodies to *T. gondii*, the antibody load decreases and will continue to decrease as IgG synthesis in the child progresses.

The production of antibody in infants with congenital toxoplasmosis varies considerably from one case to another and also is affected by treatment. Cases in which antibody production during fetal life can be demonstrated by antibody load are scarce. Early and delayed antibody production can, however, be demonstrated by the antibody load method. An example of early production is shown in Figure 31–30. During the first month of life, the titer in the infant decreases in proportion to the decrease in total IgG (curve 4). At 1 month of age, the situation is similar to that in an uninfected infant: The antibody titer and the total amount of IgG have diminished in the same proportions, and the antibody load is constant. During the second and third months, however, the antibody titer in the infected infant does not decrease at the rate expected, and the antibody load remains the same or may increase. This finding demonstrates that the IgG being synthesized by the infant contains at least as many specific antibodies to *T. gondii* as those in the maternal IgG, and this becomes obvious between the fourth and sixth months, when a definite increase in antibody titer and in antibody load occurs. In some cases, the rise in titer is not demonstrable until even later (Fig. 31–31).

The pattern observed in infants with a delayed onset of antibody response is shown in Figure 31–32. In this situation, the antibody titer remains parallel to the expected

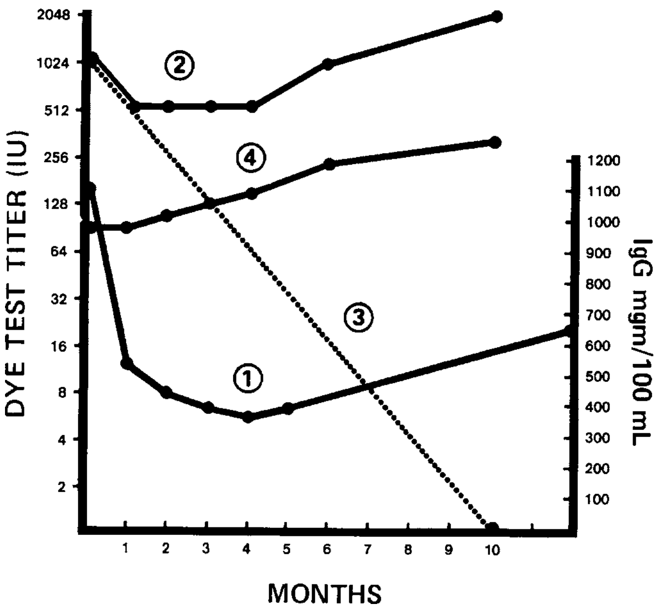

**FIGURE 31–30** Antibodies in congenital toxoplasmosis (cases with early synthesis of antibodies). Curve 1, mg of IgG/dL; curve 2, IU of *Toxoplasma* antibody per mL; curve 3, expected titer if antibodies were maternal in origin; curve 4, IU of *Toxoplasma* antibody per milligram of IgG. *(Data from Desmonts G, Couvreur J. titer of passively transferred maternal antibodies. The antibody load decreases, proving that the infant has begun to synthesize IgG, which apparently does not contain significant amounts of antibodies to *T. gondii*. This situation may persist for several months before the onset of specific antibody production is demonstrable.

Another pattern of antibody development is that observed in infants born to mothers who acquire their infection very near the time of delivery. Such infants have been identified in prospective studies [66,68]. Serologic test titers may be negative in the cord blood or be very low, especially during the first weeks of life. In such cases, the diagnosis would usually be missed and, in fact, because of the low titer in the infant, probably never suspected.

### Serologic Studies and Polymerase Chain Reaction Assay in Cerebrospinal Fluid; Polymerase Chain Reaction Assay in Urine

High titers of *T. gondii* antibodies often are observed in cerebrospinal fluid of newborns with congenital toxoplasmosis. This does not prove that antigenic stimulus or antibody formation has occurred within the CNS because the antibody load in the cerebrospinal fluid of these neonates, as a rule, is equal to that in their serum. High titers of *T. gondii* antibodies can be observed in the cerebrospinal fluid of newborns with other CNS diseases (e.g., congenital diseases due to syphilis [758] or cytomegalovirus), even when they are not infected with *T. gondii*. Because of passively transferred maternal *T. gondii* antibodies [752], and when the protein concentration is very high in the cerebrospinal fluid, the IgG concentration may reach the sensitivity level of the serologic test used. Thus demonstration of high titers of IgG antibodies in the cerebrospinal fluid in newborns is not useful diagnostically. Demonstration of IgM antibodies in the cerebrospinal fluid, especially in the absence of IgM antibodies in the serum, supports the diagnosis of *T. gondii* infection in the CNS. In contrast with this situation in the newborn, serologic testing of cerebrospinal fluid and determination of antibody load sometimes are diagnostic during infancy or childhood in patients with CNS toxoplasmosis. The diagnosis also is established if *T. gondii* antigens are demonstrable in the cerebrospinal fluid.

The method of choice for detection of the parasite in cerebrospinal fluid is PCR assay. It is both highly sensitive and specific for this purpose [435,759,760]. Fuentes and colleagues [759] detected the parasite by PCR assay in blood and cerebrospinal fluid from three of four newborns suspected of being congenitally infected with *T. gondii* and by PCR assay in urine from each of the four newborns. The investigators cautioned that because only urine from symptomatic newborns was examined, it will be necessary to assess the utility of PCR assay in urine from asymptomatic infants as well.

### Effect of Treatment

*T. gondii*-specific IgM is rarely present in serum of an infant at birth who has received treatment with pyrimethamine and sulfadiazine in utero from week 17 of gestation

until birth [76]. Data on the effects of treatment on production of IgM, IgA, and IgE antibodies are insufficient for comment [328,557,708]. Adequate data, however, are available on the effects of treatment on the dye test (IgG antibody) and antibody load method. These effects are described here. Alterations in antibody response vary among different cases and appear to depend in large part on the stage of synthesis of antibody in the child when treatment is begun.

If the infant does not begin producing antibody before treatment is started or if synthesis is at a low level, treatment apparently curbs the low-grade synthesis and prevents antibody formation. (This effect is not surprising because treatment kills the tachyzoite form, thereby halting the production of antigen.)

Data on the IgM antibody response and on the development of IgG antibody by the fetus and infant presented in this section support the hypothesis discussed earlier (see "Transmission" section) that some infants are not infected during intrauterine life but are infected during labor, from the infected placenta. The immune system of some newborns and fetuses can recognize *T. gondii* antigens with active synthesis of IgM and IgG antibodies. Once established, this synthesis of IgG and IgM antibodies does not appear to be affected by treatment. In other infants, production of *T. gondii* antibodies is delayed until maternally transmitted antibody decreases to a low titer or until specific treatment is discontinued, thereby allowing renewed proliferation of the organism. Thus in infants in whom a marked decrease in antibodies has occurred after birth, only to increase again at the age of 3 or 4 months, it seems plausible to suggest that the infection occurred not during fetal life but during labor.

The delay in antibody synthesis could be related solely to the late infection; this is substantiated by the fact that parasitemia frequently is demonstrable in cord blood or in the blood of the neonate during the first days of life (Table 31–31). Even if infection occurred during parturition, however, this explanation alone is insufficient for certain other observations. Antibodies develop readily during the first weeks of life in infants infected shortly before delivery so long as they received little or no maternal IgG antibody, whereas synthesis of antibody often is poor or completely lacking in infants whose early lesions prove that they were definitely infected during fetal life.

**TABLE 31–31** Correlation of Age of Infant and Presence of Demonstrable Parasitemia

| Age | No. of Infants | No. with Parasitemia (%) |
|---|---|---|
| Cord–1st wk | 28 | 20 (71) |
| 2nd wk | 15 | 5 (33) |
| 3rd-4th wk | 15 | 5 (33) |
| 2nd mo | 11 | 9 (0) |

*Adapted from Desmonts G, Couvreur J. Toxoplasmosis: epidemiologic and serologic aspects of perinatal infection.* In *Krugman S, Gershon AA (eds). Infections of the Fetus and the Newborn Infant. Progress in Clinical and Biological Research, vol 3. New York, Alan R Liss, 1975, with permission.*

Inhibition of fetal recognition of *T. gondii* antigen appears to offer the most satisfactory explanation for the delay in antibody synthesis observed in most infected infants. Maternal IgG is the most likely effector of this inhibitory effect. This is not solely of academic interest because such inhibition of antibody synthesis, whether by maternal IgG or by specific treatment, has important implications for the diagnosis of congenital toxoplasmosis. If treatment is begun early in these infants and is continued for some months, the diagnosis cannot be established serologically before 6 to 12 months of life.

**Serologic Rebound After Treatment.** Serologic rebound (Table 31–32) occurs commonly when pyrimethamine and sulfadiazine are discontinued [433,761,762]. In the study by Villena and associates, rebound occurred in 90% of the infants who received Fansidar, mainly 2 to 6 months after treatment was discontinued [763]. This serologic rebound suggests that although these antimicrobial agents eliminate active infection, probably through their effect on tachyzoites, not all organisms are eliminated despite 1 year of therapy. A small number of infants with very mild disease or minimal manifestations of infection, or both, have not exhibited such serologic rebound. In almost all children, serologic rebound has been asymptomatic, without changes in ophthalmoscopic findings. In one infant, however, fever, failure to thrive, and new seizures were noted in association with this serologic rebound. His illness resolved with resumption of 2 weeks of pyrimethamine and sulfadiazine therapy and did not

recur when these medications were discontinued. Thus it appears to be uncommon for symptomatic disease to develop at the time serologic rebound occurs in an infant.

These observations concerning serologic rebound have been confirmed recently in other cohorts of children [756]. Djurkovic-Djakovic and colleagues [764] found that serologic rebound occurred in 82 of 84 children (98%) without illness when medicines to treat their congenital toxoplasmosis were withdrawn at 1 year of age. The serologic profile in this rebound was IgG with a chronic-disease pattern in AC/HS and avidity tests, despite a high rate of detection of specific IgM and IgA. The serologic rebound occurred in 70% to 90% of congenitally infected children who received Fansidar/folinic acid [765]. Evidence of this phenomenon usually was noted 2 to 6 months after treatment was discontinued. Ophthalmologic surveillance during this time often did not identify recurrent chorioretinitis, although such identification has been reported [766]. It seems prudent to observe infants closely (especially by ophthalmologic examination), particularly during the months after therapy is discontinued. At present, no serologic markers have reliably been associated with recurrences of chorioretinitis in congenitally infected children. It was reported that the IgM level often was elevated with recurrences [767], but this association has not been found in the patients in the NCCCTS (see Table 31–14) [266]. More retinal lesions first identified after treatment was discontinued were noted by one group of investigators in the children infected earlier in gestation who had extraocular manifestations at birth [766].

# DIFFERENTIAL DIAGNOSIS

The diseases to be considered in the differential diagnosis of toxoplasmosis are essentially the same as those described in Chapter 23 and also should include congenital lymphocytic choriomeningitis virus syndrome [768].

# THERAPY

## General Comments

We recommend specific therapy in every case of congenital toxoplasmosis or congenital *T. gondii* infection in infants younger than 1 year of age. Insufficient data are available to allow proper evaluation of treatment in the asymptomatic infected infant. Nevertheless, most investigators, including ourselves, consider that treatment for such infants should be undertaken in the hope of preventing the remarkably high incidence of late untoward sequelae seen in children who receive inadequate or no treatment [628].

Evaluation of the efficacy of treatment of congenital *T. gondii* infection is made difficult because of the high morbidity (both early and late) and mortality rates associated with this congenital infection; most workers are understandably reluctant to perform studies that would entail withholding specific therapy. Evaluation of treatment is difficult because of variations in severity and outcome of the infection and the disease. The parasite probably is never completely eliminated by specific therapy, and cure of disease (in contrast with infection) in humans apparently depends on the strain of parasite involved, the organs infected, and the time during the course of infection when treatment is initiated. The agents that can be recommended for specific therapy at present are beneficial against the tachyzoite form, but none has been shown to effectively eradicate the encysted form, especially from the CNS and eye.

### Neuroradiologic Follow-up Evaluation After Shunt Placement

Because it has not been possible to determine with certainty at the time of presentation what the response to shunt placement and antimicrobial therapy will be, a therapeutic approach expectant for good outcome is recommended for most infants with congenital toxoplasmosis. It often is difficult to predict whether such therapy will result in brain cortical growth and expansion. A follow-up CT scan in the perioperative period after shunt placement to assess adequacy of drainage and whether subdural collections have occurred is advisable and may be useful prognostically.

## Specific Therapy

### Pyrimethamine Plus Sulfonamides

Pyrimethamine, a substituted phenylpyrimidine antimalarial drug (Daraprim), brings about not only survival but also a radical cure of animals with experimental *T. gondii* infection. The persistence of this medicine in the blood was recognized many years ago in patients who received antimalarial prophylaxis with 25-mg weekly doses. The plasma half-life in adults is approximately 100 hours [769–772]. Pyrimethamine pharmacokinetics in newborns and those younger than 1.5 years of age have been reported (Fig. 31–33) [773]. Pyrimethamine serum half-life in infants is approximately 60 hours. Pyrimethamine dosages of 1 mg/kg per day yield serum drug levels of approximately 1000 to 2000 ng/mL 4 hours after a dose. Dosages of 1 mg/kg each Monday, Wednesday, and Friday yield serum levels of approximately 500 ng/mL 4 hours after a dose. Serum levels at intervals after these two dosages are shown in Figure 31–26. Cerebrospinal fluid levels are 10% to 20% of concomitant serum levels. Phenobarbital induces hepatic enzymes that degrade pyrimethamine, and phenobarbital therapy resulted in lower serum levels and shortened the half-life of pyrimethamine. Pyrimethamine plus sulfadiazine therapy has been associated with resolution of signs of active congenital toxoplasmosis, usually within the first weeks after initiation of therapy [773]. Favorable outcomes for newborns with substantial disease (e.g., microcephaly, multiple cerebral calcifications, hydrocephalus, meningoencephalitis, thrombocytopenia, hepatosplenomegaly, active chorioretinitis) have been associated with therapy during the first year of life, which resulted in pyrimethamine levels that ranged from 300 to 2000 ng/mL 4 hours after a dose [773]. Seizures have been reported in association with pyrimethamine serum levels of approximately 5000 ng/mL (Hoff R, personal communication to McLeod R, 1986). The inhibitory concentration (IC) and cidal concentration are dependent on the assay system used, the strain of parasite, and the time over which the assay is performed [773,774]. In a

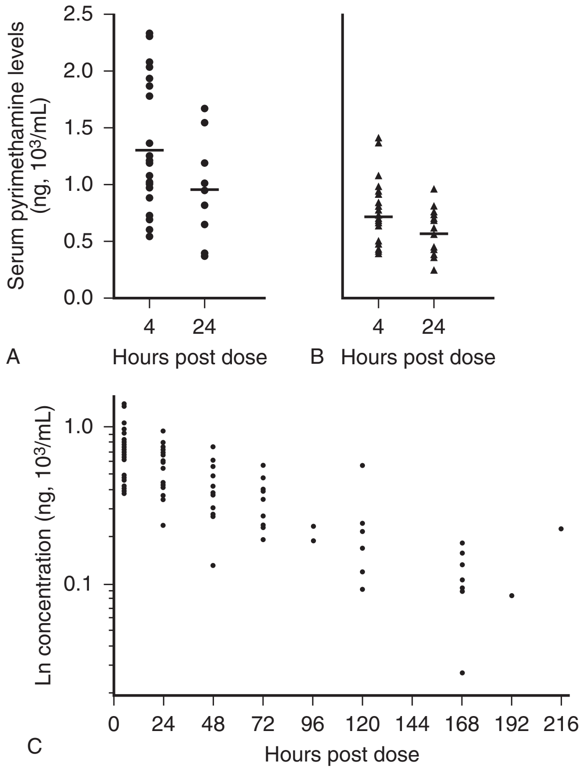

**FIGURE 31–33 Serum pyrimethamine levels obtained in infants with congenital *Toxoplasma* infection. A**, Pyrimethamine serum levels (4 and 24 hours after a dose) of children given 1 mg of pyrimethamine per kg daily. **B**, Pyrimethamine serum levels (4 and 24 hours after a dose) of children given 1 mg of pyrimethamine per kg on Monday, Wednesday, and Friday of each week. Values for children taking phenobarbital are not included. **C**, Pyrimethamine levels in sera of the entire population of infants taking 1 mg of pyrimethamine per kg on Monday, Wednesday, and Friday of each week. Values for children taking phenobarbital are not included. *(Data from McLeod R, et al. Levels of pyrimethamine in sera and cerebrospinal and ventricular fluids from infants treated for congenital toxoplasmosis. Antimicrob Agents Chemother 36:1040–1048, 1992.)*

study by McLeod and her colleagues, levels of pyrimethamine and sulfadiazine alone and in combination that inhibited growth of the type I RH strain of *T. gondii* in vitro after 24 hours were pyrimethamine $IC_{50}$, 100 ng/mL; sulfadiazine $IC_{90}$, 6.25 µg/mL; and pyrimethamine plus sulfadiazine $IC_{90}$, 25 ng/mL and 6.25 µg/mL [773].

Pyrimethamine and sulfadiazine act synergistically against *T. gondii*, with a combined activity eightfold that expected for merely additive effects [775–777]. Consequently, the simultaneous use of both drugs is indicated in all cases. Comparative tests have shown that sulfapyrazine, sulfamethazine, and sulfamerazine are about as effective as sulfadiazine [778,779]. All of the other sulfonamides tested (sulfathiazole, sulfapyridine, sulfadimidine, sulfisoxazole) are much less effective and are not recommended. For dosage recommendations, see Table 31–33. Sulfadiazine is used in addition to pyrimethamine. Appropriate dosing of pyrimethamine, sulfadiazine, and leucovorin in infants can be difficult because pediatric suspensions are not commercially available. The method shown in Figure 31–34 [433] was developed to facilitate administration of these medications to infants in the NCCCTS. It is suggested that treating congenital toxoplasmosis in infants in the United States be done in conjunction with the NCCCTS to facilitate obtaining knowledge concerning optimal medication dosages and outcome of treatment of the congenital infection and disease. The NCCCTS treatment regimen is summarized in Tables 31–33 and 31–34, and in Figure 31–34. An alternative method, which incorporates pyrimethamine, sulfadiazine, and spiramycin, formerly was used extensively for treatment in infants in France. Treatment for the fetus in utero, by maternal therapy with pyrimethamine, sulfadiazine, and leucovorin (see "Outcome of Treatment of the Fetus in Utero," later on) (Fig. 31–35), has been followed by treatment during the first year of life.

Dorangeon and coworkers studied the transplacental passage of the combination pyrimethamine-sulfadoxine (Fansidar) by measuring drug levels in mother and neonate at time of delivery [780]. They noted that the levels of pyrimethamine in the newborn were 50% to 100% and those of sulfadoxine essentially 100% of the maternal levels, depending on when the drug was last administered to the mother. The authors recognized the limitations of their study; they did not evaluate levels in the fetus at different times during gestation, when adequate drug levels are especially critical.

Villena and colleagues, in France, have reported an extensive experience with pyrimethamine-sulfadoxine treatment of congenital toxoplasmosis in the infant and in the mother when prenatal diagnosis was positive [99,763]. Although in the United States pyrimethamine-sulfadoxine is at present not recommended for use in pregnant women, newborns, or children with *T. gondii* infection, this drug combination is increasingly being used in Europe. For this reason, the studies by Trenque and colleagues in Reims, France, are summarized here [781].

To evaluate the ratio of fetal to maternal concentrations of the drugs (F/M ratio), these investigators studied placental transfer of pyrimethamine and sulfadoxine at the end of gestation in 10 women who had seroconverted during pregnancy and had been taking the drug combination by mouth twice monthly along with folinic acid. Blood samples were collected at delivery from the mother and from the umbilical vein. The F/M ratios for pyrimethamine and sulfadoxine ranged from 0.43 to 1.03 (mean $\pm$ SD $= 0.66 \pm 0.22$) and from 0.65 to 1.16 (mean $\pm$ SD $= 0.97 \pm 0.14$), respectively. The patients had steady-state drug concentrations at the time of study. Concentrations of pyrimethamine in the fetus ranged from 50% to 100% (mean 66%) of simultaneous serum concentrations in the mothers. These results agree with those obtained in monkeys by Schoondermark-van de Ven and coworkers [782]. Trenque and colleagues concluded that the effective concentrations of both drugs at 14 days after the last dose justifies twice-monthly dosing of the drug combination in cases of documented fetal infection [781].

Preliminary follow-up studies [99,763,783] suggest that such treatment with Fansidar (1.25 mg/kg of pyrimethamine each 14 or each 10 days after treatment for the fetus in utero by treatment of the mother) may lead to a lower incidence of subsequent ocular disease with fewer

**TABLE 31–33** Guidelines for Treatment of *Toxoplasma gondii* Infection in the Pregnant Woman and Congenital *Toxoplasma* Infection in the Fetus, Infant, and Older Child

| Infection | Medication | Dosage | Duration of Therapy |
|---|---|---|---|
| In pregnant women infected during gestation | | | |
| First 18 wk of gestation or until term if fetus found not to be infected by amniocentesis at 18 wk | Spiramycin* | 1 g every 8 hr without food | Until fetal infection is documented or until it is excluded at 18 wk of gestation (see also text) |
| If fetal infection confirmed after wk 18 of gestation and in all women infected after wk 24 (see text) | Pyrimethamine† *plus* | Loading dose: 50 mg each 12 hours for 2 days; then beginning on day 3, 50 mg per day | Until term‡ |
| | Sulfadiazine *plus* | Loading dose: 75 mg/kg; then beginning 50 mg/kg each 12 hr (maximum 4 g/day) | Until term‡ |
| | Leucovorin (folinic acid)† | 10–20 mg daily§ | During and for 1 wk after pyrimethamine therapy |
| Congenital *T. gondii* infection in the infant§ | Pyrimethamine†,§ *plus* | Loading dose: 1 mg/kg each 12 hours for 2 days; then beginning on day 3, 1 mg/kg per day for 2 or 6 mo§; then this dose every Monday, Wednesday, Friday§ | 1 yr§ |
| | Sulfadiazine‖ *plus* | 50 mg/kg each 12 hr | 1 yr§ |
| | Leucovorin† | 10 mg three times weekly | During and for 1 wk after pyrimethamine therapy |
| | Corticosteroids¶ (prednisone) have been used when CSF protein is ≥1 g/dL and when active chorioretinitis threatens vision | 0.5 mg/kg each 12 hr | Corticosteroids are continued until resolution of elevated (≥1 g/dL) CSF protein level or active chorioretinitis that threatens vision |
| Active chorioretinitis in older children | pyrimethamine† *plus* | Loading dose: 1 mg/kg each 12 hr (maximum 50 mg) for 2 days; then beginning on day 3, maintenance, 1 mg/kg per day (maximum 25 mg) | Usually 1–2 wk beyond the time that signs and symptoms have resolved |
| | Sulfadiazine‖ *plus* | Loading dose: 75 mg/kg; then beginning 12 hr later, maintenance, 50 mg/kg every 12 hours | Usually 1–2 wk beyond the time that signs and symptoms have resolved |
| | Leucovorin† | 10–20 mg three times weekly† | During and for 1 wk after pyrimethamine therapy |
| | Corticosteroids¶ (prednisone) | 1 mg/kg/day, divided bid; maximum 40 mg per day followed by rapid taper | Steroids are continued until inflammation subsides (usually 1–2 wk) and then tapered rapidly |

*†Adjusted for megaloblastic anemia, granulocytopenia, or thrombocytopenia; blood cell counts, including platelets, should be monitored as described in text.*

*‡Subsequent treatment of the infant is the same as that described under treatment of congenital infection. When the diagnosis of infection in the fetus is established earlier, we suggest that sulfadiazine be used alone until after the first trimester, at which time pyrimethamine should be added to the regimen. The decision about when to begin pyrimethamine/sulfadiazine/leucovorin for the pregnant woman is based on an assessment of the risk of fetal infection, incidence of false-positive and false-negative results of amniocentesis with PCR assay, and risks associated with medicines. Although reliability of PCR assay results is laboratory dependent, results from the best reference laboratories, have a sensitivity for detection of the* T. gondii *300 copy 529 base pair (bp) amniotic fluid PCR assay of 92% (see text). Thus PCR assay results reasonably determine therapeutic approach. (Data from reference (Wallon, et al, Obstet Gynecol, 2010)). With maternal acquisition of infection after 31 weeks of gestation, incidence of transmission exceeds 60%, and manifestations of infection are in general less severe. When infection is acquired between 21 and 29 weeks of gestation, management varies. After 24 weeks of gestation, we recommend that amniocentesis be performed and that pyrimethamine/leucovorin/sulfadiazine be used instead of spiramycin. Consultation with the reference laboratory is advised.*

*In France, standard of care (until late in gestation) is to wait 4 weeks from the estimated time maternal infection is acquired until amniocentesis, to allow sufficient time for transmission to occur. Amniocentesis is not performed before 17 to 18 weeks of gestation. In some instances, when maternal infection is acquired between 12 and 16 weeks of gestation or after the 21st week of gestation, pyrimethamine and sulfadiazine treatment is initiated regardless of the amniotic fluid PCR result (see text for discussion). When this approach is used, a delay in amniocentesis when maternal infection is acquired between 12 and 16 weeks and after 21 weeks of gestation would not be logical.*

*§Optimal dosage, feasibility, and toxicity currently are being evaluated in the ongoing Chicago-based National Collaborative Treatment Trial (NCTT) (telephone number 773-834-4131).*

*These two regimens are currently being compared in a randomized manner in the NCTT. Data are not yet available to determine which, if either, is superior. Both regimens appear to be feasible and relatively safe.*

*The duration of therapy is unknown for infants and children, especially those with AIDS. See section on congenital* Toxoplasma *infection and AIDS.*

*‖Alternative medicines for patients with atopy or severe intolerance of sulfonamides have included pyrimethamine and leucovorin with clindamycin, or azithromycin, or atovaquone, with standard dosages as recommended according to weight.*

*¶Corticosteroids should be used only in conjunction with pyrimethamine, sulfadiazine, and leucovorin treatment and should be continued until signs of inflammation (high CSF protein, ≥1 g/dL) or active chorioretinitis that threatens vision have subsided; dosage can then be tapered and the steroids discontinued.*

AIDS, *acquired immunodeficiency syndrome;* CI, *confidence interval;* CSF, *cerebrospinal fluid.*

**TABLE 31–34** Oral Suspension Formulations for Pyrimethamine and Sulfadiazine in the United States

***Pyrimethamine, 2-mg/mL Suspension****

1. Crush four 25-mg pyrimethamine tablets in a mortar to a fine powder.
2. Add 10 mL of syrup vehicle.[†]
3. Transfer mixture to an amber bottle.
4. Rinse mortar with 10 mL of sterile water and transfer.
5. Add enough of the serum vehicle to make a final volume of 50 mL.
6. Shake very well until this is a fine suspension.
7. Label and give a 7-day expiration.
8. Store refrigerated.

***Sulfadiazine, 100-mg/mL Suspension***[‡]

1. Crush ten 500-mg sulfadiazine tablets in a mortar to a fine powder.
2. Add enough sterile water to make a smooth paste.
3. Slowly titrate the syrup vehicle[†] close to the final volume of 50 mL.
4. Transfer the suspension to a larger amber bottle.
5. Add sufficient syrup vehicle to make a final volume of 50 mL.
6. Shake well.
7. Label and give a 7-day expiration.
8. Store refrigerated.

**Pyrimethamine: 25-mg tablets (Daraprim, Glove Wellcome Inc.) NDC #0173-0201-55.*
[†]*Syrup vehicle: suggest 2% sugar suspension for pyrimethamine. If the infant is not lactose intolerant, 2% sugar suspension can be 2 g lactose per 100 mL distilled water. Suggest simple syrup or, alternatively, cherry syrup for sulfadiazine suspension.*

sequelae than described for untreated children in the earlier literature [356,784]. Randomization, statistical analysis, or long-term follow-up appears to be lacking in these studies, and whether there was consistency in the evaluations was not specified.

Issues of dosing, pharmacokinetics, serum and tissue levels, efficacy, toxicity, and safety are relevant to considerations concerning use of Fansidar to treat congenital toxoplasmosis [785]. Sulfadoxine was found to be less active than sulfadiazine when sulfonamides were tested in vitro either alone or in conjunction with pyrimethamine against a standard laboratory strain, the type I RH strain of *T. gondii*. Concentrations of pyrimethamine alone or in conjunction with sulfadiazine that were needed to inhibit *T. gondii* were greater than 25 ng/mL [773,786]. Although the clinical relevance of these in vitro tests is not known, it seems that brain and retinal tissue trough levels (i.e., minimum levels) should exceed this minimum amount, unless both other data correlating outcomes with lower tissue levels using a variety of strains of *T. gondii* and clinical trials were to demonstrate that lower levels are beneficial. The observation that cerebrospinal fluid levels of pyrimethamine were 10% to 25% of serum pyrimethamine levels in infants with congenital toxoplasmosis therefore is relevant [773]. The serum levels of pyrimethamine following 1.25 mg of Fansidar

administered every 14 days to infants were approximately 350 ng/mL peak and 25 ng/mL trough [780]. Thus cerebrospinal fluid, brain, and retinal levels may not exceed 25 ng/mL for much of the time during which this dosage regimen is administered. Consequently, potential therapeutic brain and retinal levels may not be achieved for substantial periods with twice-monthly dosing, and thus this regimen may not be effective for treatment.

Administration of Fansidar every 2 weeks is a more convenient regimen than daily administration of pyrimethamine and sulfadiazine and is routinely used in many areas of France [785]. No hematologic toxicity was reported when this regimen was administered [763], in contrast with relatively frequent but easily reversible neutropenia (requiring frequent hematologic monitoring) in children given 1 mg/kg of pyrimethamine daily or three times each week [433,773]. Serious and life-threatening toxicity has been reported with use of Fansidar in other clinical settings, and this finding has led to reluctance on the part of some investigators and physicians to recommend its use when other medicines, especially sulfonamides with shorter half-lives, are equally or potentially more effective [786]. No such serious side effects have been reported in the studies of congenital toxoplasmosis treated with Fansidar, but although the incidence of lethal hepatotoxicity [787] is estimated to be quite low, the numbers of women and children who have received treatment with this drug to date are not sufficient to exclude the possibility that it may occur [783,788,789].

Trenque and coworkers in Reims and Marseilles, France [790], studied population pharmacokinetics of pyrimethamine and sulfadoxine in 89 children between 1 week and 13.9 years of age (weighing 3 to 59 kg) with congenital toxoplasmosis treated with Fansidar two or three times a month. The authors report that influence of weight, but not age, on pyrimethamine pharmacokinetics was significant in young children.

Both pyrimethamine and the sulfonamides are potentially toxic. Because most physicians are familiar with untoward reactions to sulfonamides (e.g., crystalluria, hematuria and hypersensitivity, marrow suppression), only the toxic effects of pyrimethamine are considered here. Serum levels of sulfadiazine were similar when the drug was administered in two or four divided doses daily to eight patients infected with HIV (mean age, 43 years; range, 38 to 56 years) [791].

### Toxic Effects of Pyrimethamine

Pyrimethamine inhibits dihydrofolate reductase, which is important in the synthesis of folic acid, thus producing reversible and usually gradual depression of the bone marrow [792,793]. Reversible neutropenia is the most frequent toxic effect, although platelet depression and anemia may occur as well. Other, less serious side effects are gastrointestinal distress, headaches, and a bad taste in the mouth. Accidental overdosing in infants has resulted in vomiting, tremors, convulsions, and bone marrow depression [794]. All patients who receive pyrimethamine should have a peripheral blood cell and platelet count twice each week. Folinic acid (in the form of leucovorin calcium) has been used to protect the bone marrow from toxic effects of pyrimethamine [162,795]. We usually administer 5 to 20 mg of leucovorin calcium each Monday, Wednesday, and Friday or even daily in infants or young children. The usual dosage in older children and adults is 10 to 20 mg/day orally.

Data suggesting that oral leucovorin calcium can be used to reverse the toxic effects of pyrimethamine have been presented. Nixon and Bertino clearly demonstrated that leucovorin calcium in tablet form was well absorbed (in adult subjects), thereby expanding the serum pool of reduced folates [796]. Under fasting conditions, the quantitative absorption of the orally administered preparation was close to 90%. The parenteral form (calcium leucovorin used for injection) may be ingested with equal effectiveness (Masur CJ, Lederle Laboratories, written communication to Remington JS, 1975). These substances, in contrast with folic acid, do not appear to inhibit the action of

pyrimethamine on the proliferative form of *T. gondii* because of an active transport mechanism for folinic acid [797], and thus may be used in conjunction with the latter drug to allay toxicity.

Garin and colleagues used Fansidar in a small number of infants and consider this agent to be well tolerated, with a much simpler treatment regimen [798–800]. This antimicrobial combination is now widely used in Europe. The potential for serious toxicity of medication with a half-life as long as that of sulfadoxine has led others to avoid this regimen. Whether its potential for toxicity is as great in infants as in adults is not known.

### Teratogenic Effects of Pyrimethamine

In experiments with pyrimethamine, Thiersch reported an effect on rat fetuses ranging from stunting to death, depending on the amount of pyrimethamine administered to the mothers during pregnancy [801]. The effect on the fetuses could be moderated, with a higher yield of live litters but also of stunted and malformed animals, when the mother was given leucovorin calcium at the time of drug administration. The malformations resulted from enormous doses (e.g., 12 mg/kg, compared with the usual dose in humans of 0.5 to 1 mg/kg) and were similar to those obtained with closely related folic acid analogues: general stunting of growth, general hydrops, cranial bone defects, incomplete cranial and brain development, rachischisis, internal hydrocephalus, ventral hernias, situs inversus, and combinations of all of these. An even more severe teratogenic effect was reported in the studies of Anderson and Morse, who similarly employed doses far higher than could ever be employed in humans [802]. Similar studies in rats are those of Dyban and associates [803,804]. In another study in rats, Krahe used doses more comparable to those employed in humans and noted fetal resorption but no teratogenic effects after large doses of pyrimethamine [805]. In 1971, Sullivan and Takacs pointed out the lack of comparative data on the teratogenic effects of pyrimethamine in different mammalian species [806]—a lack that adds to the difficulty in estimating the extent of teratogenic risk in humans. Their results in rats and hamsters emphasize the shortcomings of attempts to determine a safe clinical dose on the basis of tests limited to a single species of test animal. The drug was less teratogenic in golden hamsters than in Wistar rats. About 70% of rat fetuses were dead or malformed (the malformations included brachygnathia, cleft palate, oligodactyly, and phocomelia) as a result of administration of single oral doses of 5 mg (approximately 20 mg/kg) to pregnant females. Less than 10% of hamster fetuses died or were malformed after similar doses that on a milligram-per-kilogram basis were eight to nine times greater than those given to rats. Repeated doses nearer to those used in humans also were teratogenic in rats but not in hamsters. These investigators also demonstrated that folinic acid can significantly reduce the incidence of dead and malformed fetuses when administered during pyrimethamine treatment.

Puchta and Simandlova, using doses of 2, 5, and 10 mg/kg in rats, could demonstrate no malformations in rat fetuses [807]. Their results are in marked contrast with those of most other workers, and the differences remain to be explained.

In all of these studies, pyrimethamine was administered during the period of early organogenesis, which is the period of maximum susceptibility to damage by teratogenic agents.

## Spiramycin

Spiramycin, a macrolide antibiotic that is available to physicians in the United States only by request to the FDA, has an antibacterial spectrum comparable to that of erythromycin and is active against *T. gondii*, as demonstrated in animal experiments [808,809]. In vitro studies also have been reported [810]. The actual concentration necessary to inhibit growth of or kill the organism is unknown. It has been described as having exceptional persistence in the tissues [811,812] in comparison with erythromycin, oleandomycin, or carbomycin. Such high tissue levels may account for the observations that spiramycin is much more active in vivo against susceptible bacteria than is erythromycin, despite higher serum levels attained with comparable doses of erythromycin and greater sensitivity of the bacteria to erythromycin in vitro [813]. A review of this antimicrobial agent has been published [814].

Spiramycin is supplied as a syrup and in capsules. The usual daily dose in adults is 1 g, three times a day. Garin and coworkers studied drug concentrations in serum, cord serum, and placenta in pregnant women [815]. On a daily regimen of 2 g by mouth, the average levels were 1.19 μg/mL (range, 0.50 to 2.0 μg/mL), 0.63 μg/mL (range, 0.20 to 1.8 μg/mL), and 2.75 μg/mL (range, 0.70 to 5.0 μg/mL), respectively. On a dosage schedule of 3 g daily, the results were 1.69 μg/mL (range, 1 to 4 μg/mL), 0.78 μg/mL (range, 0.75 to 2.0 μg/mL), and 6.2 μg/mL (range, 3.25 to 10 μg/mL), respectively. (These serum levels in the mother are similar to those obtained by Hudson and colleagues at 2 and 4 hours after a given dose in persons receiving 1 g every 6 hours [816]. Thus a total dose of 3 g daily resulted in levels in the placenta that were twice as high as those attained with a total dose of 2 g daily. (This is one reason for the recommendation of 3 g administered as a 1-g thrice-daily dose during gestation.) In both regimens, the concentration in cord serum was approximately one half and the placental levels approximately three to five times greater than the level in the corresponding maternal serum. The investigators stated that the levels achieved in the placenta are ample for treatment of *T. gondii* in that organ, but whether the levels in cord serum are sufficient for treatment of the fetus in utero remains to be verified. Forestier and associates published another study of spiramycin concentrations in the mother and the fetus (fetal blood sampling) [817].

Spiramycin pharmacokinetics exhibits individual variation. Fetomaternal concentrations were studied in 20 cases of maternal infection acquired between weeks 3 and 10 of pregnancy and treated with a daily dose of 3 g. The maternal plasma concentrations of spiramycin were $0.682 \pm 0.132$ mg/L in the first month of treatment; $0.618 \pm 0.102$ mg/L during weeks 20 to 24 of pregnancy; and $1.015 \pm 0.22$ mg/L in the sixth month. The mean fetal concentration was 0.290 mg/L during weeks 20 to

24 of pregnancy (i.e., 47% of maternal values), with a lack of correlation between mothers and fetuses. At birth, the placental concentration (2.3 μg/mL) was four times the average blood concentration in mothers (0.47 mg/L) and six and one half times the cord blood values (0.34 mg/L). A good correlation was found between maternal blood and placental values, and a fair correlation between cord blood and placental values. These facts suggest that monitoring of spiramycin treatment by measuring maternal spiramycin blood concentrations might be useful in determining effective individual dosage [69].

Very little definitive information is available on the efficacy of spiramycin in congenital toxoplasmosis in the newborn. In a study of 12 cases (mainly of severe clinical disease) by Martin and coworkers in which spiramycin was employed, the data are impossible to interpret because tetracyclines, pyrimethamine, sulfonamides, and corticosteroids frequently were also used in the same infants [818].

In a carefully designed study by Beverley and colleagues, congenitally infected mice were given spiramycin or a combination of sulfadimidine and pyrimethamine from the age of 4 to 8 weeks [819]. The levels of spiramycin in the heart, liver, kidney, and spleen were approximately 50 to 140 times greater than the serum levels after 4 weeks of treatment. Both treatment regimens were effective in preventing the histopathologic changes noted in congenitally infected mice not given treatment. Regardless of the form of treatment, a smaller number of cysts were found in the brains of mice that received treatment than in those of mice receiving no treatment (probably because treatment prevented the development of new cysts, rather than destroying cysts formed before initiation of therapy). The authors suggested that because spiramycin was as effective as the potentially toxic combination of pyrimethamine and sulfadimidine, it will be found to be preferable to the combination agent in treatment of congenital toxoplasmosis.

Because the optimal dose and route of administration of spiramycin in infants and adults have never been established for toxoplasmosis, the study by Back and coworkers on the pharmacology of parenteral spiramycin as an antineoplastic agent is pertinent [820]. Twelve patients with various types of far-advanced neoplastic diseases were given daily intravenous doses ranging from 5 to 160 mg/kg. Doses greater than 35 mg/kg produced local vasospasm, a feeling of coolness, strange taste, vertigo, dizziness, flushing of the face, tearing of the eyes, nausea, vomiting, diarrhea, and anorexia. No hematologic toxicity, electrocardiographic changes, or impairment of liver or kidney function were noticed. Of note, Q-T interval prolongation and life-threatening arrhythmias (cardiac arrest) were reported in two neonates receiving spiramycin (300,000 IU/kg per day by mouth) [821]. The infants recovered completely after immediate cardiopulmonary resuscitation maneuvers.

At present, the only indication for which we use spiramycin is in the actively infected mother to attempt to reduce transmission to her fetus [822]. It should be noted that spiramycin failed to prevent neurotoxoplasmosis in immunosuppressed patients [823]. Spiramycin may reduce the severity of infection in a fetus because it delays transmission to a later time in gestation when transmission is associated with less severe manifestations of infection. Lacking are data that conclusively demonstrate efficacy of spiramycin in treatment of the infected fetus. The controversy of whether spiramycin prevents transmission of *T. gondii* to the fetus is discussed later under "Serologic Screening" in the "Prevention" section. The subject has more recently been commented on by Montoya and Liesenfeld [824].

### Other Drugs

At present, no clinical data are available to allow for recommendation of any of the drugs described next for treatment of the immunocompetent pregnant patient, fetus, or newborn.

**Trimethoprim Plus Sulfamethoxazole.** Despite reports of successful treatment of murine toxoplasmosis with a combination of trimethoprim and sulfamethoxazole (TMP-SMX) [825,826], trimethoprim alone has been found to have less effect against *T. gondii* both in vitro and in vivo [827–830]. The combination of this drug with sulfamethoxazole is synergistic in vitro [826] but is significantly less active in vitro and in vivo than the combination of pyrimethamine and sulfonamide. Previously, a number of reports have described use of the combination in human toxoplasmosis, but whether the effect of the combination was due solely to the sulfonamide component was unclear [831–833]. A recent, randomized trial of TMP-SMX versus pyrimethamine-sulfadiazine in toxoplasmic encephalitis in patients with AIDS by Torre and colleagues [834] revealed that TMP-SMX was a valuable alternative to pyrimethamine-sulfadiazine for that purpose. In Brazil, TMP-SMX was reported to reduce the incidence of recurrent toxoplasmic chorioretinitis in 61 patients, compared with that in 63 control patients (mean ages 26 ± 10 versus 27 ± 11 years [range, 7 to 53 years]) [209,835]. Nevertheless, we do not recommend its use in the infected fetus or newborn in the absence of carefully designed trials that reveal efficacy of TMP-SMX in congenital toxoplasmosis. When parenteral therapy is essential because of gastrointestinal disease, TMP-SMX may provide a temporizing alternative treatment.

**Clindamycin.** Clindamycin has been shown to be effective in treatment of murine toxoplasmosis [836,837] and ocular infection in rabbits [838]. Studies are needed, however, before it can be recommended for routine treatment of congenital infection in infants or pregnant women. When this antibiotic has been used in combination with pyrimethamine in patients with AIDS who have toxoplasmic encephalitis, results have been comparable to those with pyrimethamine-sulfadiazine treatment [839,840].

**Tetracyclines.** Both doxycycline [841] and minocycline [842,843] have efficacy in the treatment of murine toxoplasmosis. Doxycycline was used successfully in two patients with AIDS who had toxoplasmic encephalitis when it was administered at 300 mg per day intravenously in three divided doses [844]. When doxycycline was given orally at doses of 100 mg twice a day in six of the patients who were intolerant to pyrimethamine-sulfadiazine, five

patients had associated neurologic and radiologic recurrences while receiving the drug [845]. Further study of the tetracyclines in the treatment of toxoplasmosis in adults is likely to involve their use in combination with other antimicrobial agents. No data are available on their use in the newborn or young children with toxoplasmosis, nor are they recommended for this purpose.

**Rifampin.** Rifampin in high doses was not effective against *T. gondii* in a murine model [846].

**Macrolides.** Macrolides-roxithromycin [847,848], clarithromycin [849], and the azalide azithromycin [850] have been shown to have activity against *T. gondii* in vivo in a mouse model. Stray-Pederson studied levels of azithromycin in placental tissue, amniotic fluid, and maternal and cord blood [851]. Levels in maternal serum ranged from 0.017 to 0.073 mg/mL (mean, 0.028 mg/mL). Whole blood levels were higher (mean, 0.313 mg/mL). Mean levels in amniotic fluid and cord blood were 0.040 and 0.027 mg/mL, respectively. Placental levels were higher (mean, 2.067 mg/mL). It should be understood, however, that azithromycin is concentrated in tissues and intracellularly; thus, levels at these sites probably are of greater clinical importance than serum or blood levels.

When used in combination with pyrimethamine, both clarithromycin and azithromycin have been successful in treating toxoplasmic encephalitis in adult patients with AIDS [515]. In non-AIDS patients, the combination of pyrimethamine plus azithromycin has been reported by Rothova and colleagues to be equal in efficacy to pyrimethamine plus sulfadiazine measured as time to resolution of active eye disease in patients with recurrent chorioretinitis [852,853]. Ketolides also are active both in vitro and in vivo in the mouse model of toxoplasmosis [244,854,855].

**Atovaquone.** Atovaquone has been reported to have potent in vitro activity against both tachyzoite and cyst forms [856,857]. It significantly reduced the mortality rate in murine toxoplasmosis and had remarkable, although differing, activity against different strains of *T. gondii* [856]. Atovaquone has been used in AIDS patients with toxoplasmic encephalitis with encouraging results [858,859]. Unfortunately, relapse occurred in approximately 50% of patients in whom atovaquone was used for acute therapy and continued alone as maintenance therapy [858,859]. Seventeen of 65 patients (26%) who received atovaquone as a single agent for maintenance therapy of toxoplasmic encephalitis experienced a relapse [860]. The combination of pyrimethamine and atovaquone may prove more useful [858]. Serum levels of atovaquone in patients with toxoplasmic encephalitis were not predictive of clinical response or failure [860].

Bioavailability of the drug is improved when medication is ingested with food. The reliability of absorption of this drug continues to be a problem. Survival time was significantly better among those patients with higher steady-state plasma concentrations of the drug [859,858]. Although a new formulation of atovaquone is reported to achieve higher plasma concentrations, prospective trials are needed to compare the efficacy of this drug with that obtained in standard drug regimens. This drug should never be used alone for the treatment of the acute infection, but rather it should be given in combination with drugs such as pyrimethamine. The adverse effects observed in these studies included hepatic enzyme abnormalities (50%), rash (25%), nausea (21%), and diarrhea (19%) [860]. Between 3% and 10% of patients receiving atovaquone were reported to discontinue the drug because of rash, hepatic enzyme abnormalities, nausea, or vomiting [858,860]. Leukopenia associated with the combination of pyrimethamine and atovaquone has responded to folinic acid (leucovorin) and granulocyte colony-stimulating factor therapy [858].

Recently, Meneceur and colleagues [861] demonstrated that the susceptibility in vitro to pyrimethamine, sulfadiazine, and atovaquone among 17 strains of *T. gondii* belonging to various genotypes varied.

**Fluoroquinolones.** A number of fluoroquinolones have been found to be active against *T. gondii* in vitro and in vivo in a mouse model of the acute infection. Their activity may be enhanced when used in combination with pyrimethamine, sulfadiazine, clarithromycin, or atovaquone [855,862,863].

## DURATION OF THERAPY

The optimal duration of therapy in congenitally infected infants is not known. Among infants who were given the combination of pyrimethamine and sulfadiazine for relatively brief periods, untoward sequelae of the disease subsequently developed [864,865]. We, and other investigators (including our colleague J. Couvreur in Paris), recommend that therapy be continued for 1 year, as outlined in Tables 31–33 and 31–34. We recommend using the combination of pyrimethamine and sulfonamide for the entire 1-year period.

In some areas of Europe, treatment is continued for the first 2 years of life. We have not noted active disease or progression of signs or symptoms when treatment is discontinued when children are 1 year of age. For the special issue of treatment of the HIV- and *T. gondii*-infected newborn of an HIV-infected mother, see "Congenital *Toxoplasma gondii* Infection and Acquired Immunodeficiency Syndrome" earlier under "Clinical Manifestations."

### Treatment of the Fetus Through Treatment of the Pregnant Woman

For additional pertinent information, see "Prevention of Congenital Toxoplasmosis Through Treatment of the Pregnant Woman" and Table 31–33. When the diagnosis of infection in the fetus is established earlier than 17 weeks, we suggest that sulfadiazine be used alone until after the first trimester, at which time pyrimethamine should be added to the regimen. The decision about when to begin pyrimethamine/sulfadiazine/leucovorin for the pregnant woman is based on an assessment of the risk of fetal infection, incidence of false-positive and false-negative results of amniocentesis with PCR, and risks of medicines. Although reliability of PCR results are laboratory dependent, results from the best reference laboratories, have a sensitivity for PCR of the *T. gondii* 300 copy 529

repeat gene with amniotic fluid of 92% (See earlier). Thus PCR results reasonably determine the therapeutic approach.

When the mother becomes infected between 22 and 29 weeks of gestation, the incidence of transmission exceeds 50%, manifestations of infection in the fetus are substantial. With maternal acquisition of infection after 31 weeks of gestation, incidence of transmission exceeds 60%, manifestations of infection are in general less severe.

When infection is acquired between 21 and 29 weeks of gestation, management varies. After 24 weeks of gestation, amniocentesis may be performed and pyrimethamine/leucovorin/sulfadiazine may be used instead of spiramycin. In the United States, Consultation with the Palo ALto reference laboratory (650-326-8120. *Toxoplasma* serology) or others with expertise is advised.

In France, standard of care (until late in gestation) is to treat women with newly acquired *T. gondii* infection as soon as the diagnosis is established, but to wait 4 weeks from the estimated time that maternal infection was acquired to perform amniocentesis to allow sufficient time for transmission to occur. Amniocentesis is not performed before 17 to 18 weeks of gestation. In some instances, when maternal infection is acquired between 12 and 16 weeks of gestation or after the 21st week of gestation, pyrimethamine and sulfadiazine treatment is initiated regardless of the amniotic fluid PCR result (see text for discussion). When this approach is used, a delay in amniocentesis when maternal infection is acquired between 12 and 16 weeks and after 21 weeks of gestation would not be logical.

With the advent of prenatal diagnosis (see earlier discussion), attempts are being made to provide treatment for the infected fetus of mothers who have decided to carry their pregnancy to term by treatment of the mother with pyrimethamine and sulfadiazine. Couvreur, in close cooperation with Daffos and colleagues, has made certain observations that should prove helpful [822]. Their data suggest that spiramycin, although effective in reducing the frequency of transmission of the organism from mother to fetus, does not alter significantly the pathology of the infection in the fetus. For this reason, after week 17 of gestation, they treat with pyrimethamine-sulfadiazine for the duration of pregnancy when fetal infection has been proved or is highly probable. (In a commentary, Jeannel and coworkers raise the question of whether spiramycin was of value in the pregnancies studied by Daffos and colleagues.) [866] During this treatment period, the mother is carefully monitored for development of hematologic toxicity. If significant toxicity appears despite treatment with folinic acid, the drug combination is discontinued until the hematologic abnormalities are corrected and the drug regimen is then restarted. In their opinion, pyrimethamine (in combination with sulfonamides) appears to be the most efficacious treatment for infection in the fetus and newborn. Whether it has untoward toxic effects on the fetus, even after organogenesis has occurred, is unknown. Of importance, use of this drug combination in pregnant women has been reported to substantially reduce the subsequent clinical manifestations of the infection in the newborn and the antibody response of the fetus. Therefore, it is critical to understand that when the mother receives pyrimethamine and sulfadiazine, and the infant appears normal, that infant may or may not be infected. Thus if infection of the fetus was not established before in utero treatment was initiated, and the infant is clinically normal, determination of whether the infant should receive treatment throughout the first year of life is difficult. Following maternal treatment, no signs of infection may be detectable in the infant at birth, but untoward sequelae may develop in later months or years. In addition, the infected newborn may not have the typical clinical or serologic features of the congenital infection. This situation creates a serious dilemma in trying to determine whether such infants should receive treatment when they are born to mothers who received treatment during pregnancy. Thus use of pyrimethamine plus sulfadiazine cannot be recommended as routine in every woman who acquires the acute infection during pregnancy.

Because of the potential for this dilemma, if there is no contraindication to performing the procedure and diagnosis is uncertain we consider it important to employ amniocentesis to determine whether the fetus is infected in cases of *T. gondii* infection acquired before the last trimester of pregnancy. Demonstration of fetal infection will allow for this combination drug regimen to be chosen for the mother and the neonate. If, however, extenuating circumstances preclude prenatal diagnosis in a mother whose infection was proved to have occurred during the second or third trimester, the same course of treatment as that used for cases in which the diagnosis has been established in the fetus may be considered because infection acquired during the second trimester is associated with the highest risk for fetal disease, and in the third trimester, with the highest rate of transmission to the fetus.

The original report by Daffos and colleagues in 1988 was the first to highlight the importance of attempting to treat the infection in the fetus to improve clinical outcome [82]. In 24 of the 39 cases of proven infection, pregnancy was terminated at the request of the mother. Toxoplasmic encephalitis was noted in each of these 24 fetuses, including those in whom the findings on ultrasound examination were normal when the pregnancy was terminated. In every case, extensive necrotic foci were present, which suggested that sequelae might have been severe were the pregnancy not terminated. These findings also strongly suggest that early transmission (before week 24) usually results in severe congenital toxoplasmosis rather than subclinical infection (see Table 31–9).

In 15 of the 39 cases of diagnosed infection, the mother decided to continue her pregnancy. In these women, maternal infection was acquired between weeks 17 and 25 of gestation; in these cases, fetal ultrasound examination results were normal. Treatment with sulfonamides and pyrimethamine was begun as soon as the diagnosis of fetal infection was established, between 8 and 17 weeks after acquisition of the infection by the mother. After delivery, the presence of congenital *T. gondii* infection was demonstrated in the 15 newborns (in one infant, the serologic test result turned totally negative but became positive again a few weeks after treatment was discontinued, indicating that the infection was only suppressed, not eradicated). The 15 infants were asymptomatic despite the presence of cerebral

calcifications in 4. Funduscopic appearance was normal, as were findings on the cerebrospinal fluid examination. Children were given pharmacologic treatment after birth, and all remained asymptomatic without neurologic signs or mental retardation. Ocular fundi remained normal in 13 children; retinal lesions were noted in 1 child at 4 months of age and in another at 18 months of age. The duration of follow-up was 3 to 30 months. Thus despite rather early (before week 26) transmission of parasites from mother to fetus, infection remained either subclinical or mild in those fetuses whose mothers received pyrimethamine and sulfonamide treatment during pregnancy. Positive findings at prenatal diagnosis should be considered an indication for this therapeutic regimen, which would not usually be considered because of its potential toxicity to both fetus and mother. It should be understood that for ethical reasons, controlled trials (with "treatment" and "no treatment" groups of patients) have not been performed and may not be performed if an untreated group is required. Thus one is left with studies in which historical data are used for comparison. Comparative trials likely will be performed in the future as newer therapies are developed or to contrast outcomes of the present approach with prompt initiation of treatment without amniocentesis, especially for early gestation infections.

### Subsequent Studies

Couvreur and colleagues studied the outcome in 52 cases of congenital *T. gondii* infection diagnosed by prenatal examination in mothers who then were given the pyrimethamine, sulfadiazine, and spiramycin treatment regimen described by Daffos and colleagues [76,82]. Results in these infants were compared with those obtained in 51 infants with congenital toxoplasmosis whose mothers had received only spiramycin. Treatment for the infants after birth was the same in both groups. Although these two groups were not strictly comparable, valuable information can be gleaned from such a comparison so long as the focus remains on the qualitative direction of the results, rather than on the quantitative data. Remarkable were the lesser number of isolates from the placentas, the lower IgG antibody titers at birth and at 6 months of age, the lower prevalence of positive IgM antibody tests, and the higher number of subclinical infections in the offspring of mothers who received the pyrimethamine-sulfadiazine regimen. These data further support those discussed earlier—that treatment of the fetus is possible and that such treatment may result in a more favorable outcome if pyrimethamine—sulfadiazine is in the regimen (Table 31–35) [822].

Boulot and colleagues [867] described two cases in which women with *Toxoplasma* infection diagnosed during pregnancy subsequently received treatment with pyrimethamine plus sulfadiazine alternated with spiramycin, as described by Daffos and coworkers. Despite prolonged maternal treatment, the infants born to these women had congenital toxoplasmosis; *T. gondii* was isolated from the placentas. Although the success of treatment in the fetus will depend on a number of variables, as discussed earlier, these results serve as a note of caution in regard to the information given to parents about the effectiveness of such prenatal treatment.

In 1989, Hohlfeld and colleagues [76] updated information published earlier by their same group [82]. Because these were the first such available data, and although only relatively short-term follow-up is provided, a reasonably comprehensive presentation of their data seems justified. They reported 89 fetal infections in 86 pregnancies (39 of these infected fetuses were included in the original report by Daffos and coworkers, discussed earlier). All of the women were given spiramycin, 3 g daily, throughout their pregnancy from the time maternal infection was proved or strongly suspected on the basis of serologic studies until fetal infection was documented or considered to be highly likely. Spiramycin treatment was instituted a mean of 36 ± 27 days after the estimated onset of infection. At prenatal examination, 80 of these women had had positive specific test results, and the remaining 9 had evidence of congenital *T. gondii* infection at birth. When fetal infection was confirmed, 34 terminations were performed at the request of the parents. The mean interval between infection and the beginning of therapy for continued pregnancies was remarkably and significantly shorter than for terminated pregnancies. The terminations were considered if severe lesions (marked hydrocephaly) were present on ultrasonogram at the time of prenatal diagnosis or when maternal infection had occurred very early in pregnancy. The main reason for termination was demonstration of cerebral lesions on ultrasonograms. Of interest is that the evolution

of hydrocephalus was remarkably rapid in some of the cases, with ventricular dilation observed to develop within 10 days. (Ventricular dilation is an indirect sign of the presence of lesions due to *T. gondii*.) For most of the 52 pregnancies allowed to continue, treatment with pyrimethamine and sulfadiazine for 3 weeks alternating with spiramycin for 3 weeks was instituted, along with folinic acid (leucovorin). In 47 of 54 cases, postnatal treatment consisted of courses of pyrimethamine and sulfadiazine alternating with spiramycin, except in 3 infants, in whom only spiramycin was used. The mean period of follow-up was 19 months (range, 1 to 48 months).

In that study, subclinical infection was defined as complete absence of symptoms. The benign form included isolated subclinical signs, including intracerebral calcifications, normal neurologic status, and chorioretinal scars without visual impairment. This form was found mainly in older infants observed during the follow-up period and in younger infants when retinal scars were peripheral and did not involve the macular region (Hohlfeld P, personal communication to Remington JS, 1993). The severe form included hydrocephaly, microcephaly, bilateral chorioretinitis with impaired vision, and abnormal immunologic findings.

The overall risk of fetal infection was 7%, and this risk varied with time of maternal infection, as shown in Table 31–6. A more complete breakdown by week of gestation was published by the same group of investigators in 1994 (see Table 31–7) [77]. At prenatal diagnosis, the nonspecific signs were not predictive of the severity of the fetal lesions; they were not found to differ significantly when subsequently terminated pregnancies were compared with those pregnancies that were allowed to continue. Fifty-five infants were born of the 52 pregnancies that were allowed to continue; no intrauterine growth retardation was noted. The findings are shown in Table 31–36. Each of the seven infants with cerebral calcifications had normal findings on ophthalmologic and neurologic examinations (benign form).

Attempts at isolation of the parasite from the placenta were positive in 23 cases, negative in 20, and inconclusive in 3; isolation was not attempted in 9 cases. Cord blood was positive for IgM antibodies in 8 cases, negative in 46 cases, and not examined in 1 case.

| Abnormal lumbar puncture | 1/54 | 2 |
| Evidence of infection on inoculation of placenta | 23/46 | 50 |
| Positive cord blood IgM antibody | 8/53 | 15 |

**Numerator = number of abnormalities present at birth; denominator = total number of infants examined for abnormalities.*
*Adapted from Hohlfeld P, et al. Fetal toxoplasmosis: outcome of pregnancy and infant follow-up after in utero treatment. J Pediatr 115:767, 1989, with permission.*

Follow-up evaluation was for 6 months to 4 years in 54 of the infants. The overall subclinical infection rate was 76%. The outcomes are shown in Table 31–37, where they are compared with those in historical controls from a study performed from 1972 to 1981 [868].

The additional information provided by this publication [76] further supports and extends the indirect evidence these authors published earlier [82], that such treatment of the fetus reduces the number of biologic signs at birth and can reduce the likelihood of severe damage in the newborn. Thus prenatal management as discussed by Hohlfeld and colleagues and previously by Daffos and coworkers appears to have resulted in an increase in the proportion of subclinical infections in first- and second-trimester infections, and in a reduction of severe congenital toxoplasmosis and a shift from benign forms to subclinical infections. In the earlier study, a large percentage of the cases had been third-trimester infections, which are known to have a better prognosis. Hohlfeld and colleagues recognized that their superior results, at least in part, may have been due to accurate diagnosis and selective termination in the few cases in which the fetuses were severely affected (2.7% of all referred cases in their experience), and to the effect of spiramycin on prevention of congenital transmission and the apparent reduction in the severity of fetal infection associated with the regimen of pyrimethamine-

sulfadiazine. In Hohlfeld and colleagues' series, only 4% were third-trimester infections because, in the first years of their experience, prenatal diagnosis was not performed for late infections during gestation. Now that more rapid methods are available for diagnosis, the authors consider that prenatal diagnosis and treatment also may be appropriate in the third trimester.

### *Outcome of Treatment of the Fetus in Utero*

Outcome was not uniformly favorable [738] when the algorithm of Daffos and coworkers [82] and Hohlfeld and colleagues [76] for patient care was applied. As mentioned earlier, part of the favorable outcome of Hohlfeld and colleagues can be attributed to termination of pregnancies in which the fetus had severe involvement (e.g., hydrocephalus). Nonetheless, the individual outcomes reported are better than would have been expected for first-trimester and early second-trimester infections. Almost all of the infected children from pregnancies managed according to this algorithm have demonstrated normal development, and those who have had clinical signs do not appear to have manifestations associated with significant impairment of normal function [76]. Thus at present, the approach of Daffos and Hohlfeld and their coworkers [76] appears to provide the best possible outcome.

In this series, 148 fetal infections occurred in 2030 cases of maternal infection. The only predictive feature for fetal infection was fetal gestational age at onset of infection: For infection at less than 16 weeks, 31 of 52 (60%) fetuses had ultrasonographic evidence of infection. Possible abnormal findings included ascites, pericarditis, and necrotic foci; 48% had cerebral ventricular dilation. If pregnancy was terminated, large areas of necrosis in the fetal brain were noted at fetopathologic examination. For pregnancies terminated at 17 to 23 weeks of gestation, 16 of 63 (25%) infected fetuses had signs on ultrasonographic examination; 12% had ventricular dilation. For pregnancies terminated later than 24 weeks, 1 of 33 fetuses had signs on ultrasonographic evaluation. Hydrocephalus was not observed. Thus these investigators offer termination at less than 16 weeks of gestation (See Table 31–8).

In the Paris studies, when mothers were found to be infected well before 16 weeks of gestation (i.e., in the first weeks of gestation) and the fetus was found to be infected by amniocentesis at 17 to 18 weeks of gestation, many of the pregnancies were terminated. Almost uniformly the fetus was found to have brain necrosis; 48% had cerebral ventricular dilation (see Table 31–8) [82]. By contrast, Wallon and coworkers [869] do not terminate pregnancies of women who are acutely infected after 13 weeks of gestation, and who receive treatment, unless fetal brain ultrasonographic findings are markedly abnormal. Their approach is based on the fact that most infected children in their series were not severely impaired. In their experience with 116 congenitally infected children, only 2 children (2%) demonstrated some degree of visual impairment due to macular lesions, and these children had no neurologic or mental deficits. In this series, 31 (27%) were found to have cerebral calcifications or retinal lesions, but these children were neurologically and developmentally normal and without severe impairment of vision.

Mirlesse (personal communication to the authors, 1998 and 2004) described the outcome in 141 infected fetuses without cerebral dilation who received both prenatal and postnatal treatment. Neonatal data were available in 133 cases, and 104 children were observed for a mean of 31 months. Two children died of malignant hyperthermia, 1 child had seizures, 1 child had a psychiatric disorder, and 12 had new eye lesions that developed between 6 months and 2 years of age. Sixteen (12%) of 133 children had eye lesions when they were born (Table 31–38).

Prenatally, fetal ultrasound examinations were performed fortnightly, and head ultrasonographic evaluations and sometimes brain CT also were performed in the newborn period for some of the infants. The prenatal ultrasonographic evaluation was performed through the endovaginal route, using a 7-MHz probe, when there was a cephalic presentation of the fetus.

Of 133 children, hyperechogenic areas (HEAs) were present in 37 (26%), and HEAs were identified antenatally in 17 of 37 (46%). HEAs were never seen before 29 to 30 weeks of gestation. Ultrasound examinations underestimated lesions identified by CT at birth in 6 cases.

An important finding was that more fetuses demonstrated HEAs on CT scans if there was a longer interval between diagnosis of maternal and fetal infection (see Table 31–38). This finding could be explained in two alternative ways. It could be that longer delays in diagnosis and treatment were associated with infections acquired earlier in gestation when disease is more severe and thus there are more associated sequelae. Alternatively, more rapid diagnosis and treatment reduced sequelae.

Another important implication of these investigators' findings is that HEAs and their correlation with more frequent ophthalmologic disease demonstrate homogeneity of neurosensory involvement. In the NCCCTS, this frequent concordance of neurologic and ophthalmologic involvement also was noted. HEA predicts ophthalmologic abnormalities, but such abnormalities are not always present. Developmental outcome in these children who received treatment, whether HEAs were present or not, was normal (see Table 31–38).

## Sequelae of Congenital Toxoplasmosis in Children Who Received No Treatment

### *Stanford-Alabama Study*

Results of a collaborative study performed in the United States suggest that adverse sequelae develop in a very significant number of children born with subclinical congenital *T. gondii* infection [361]. In this study, the children were divided into two groups on the basis of indications for which serologic studies for toxoplasmosis were initially performed. Group I consisted of 13 children: Of these, 8 cases were detected as a result of routine screening of cord serum for IgM *T. gondii* antibodies [328] and as a result of testing for IgG and IgM antibodies to *T. gondii*. These tests were performed either because acute *T. gondii* infection was diagnosed during pregnancy or at term in the mother or because the children were screened for nonspecific abnormalities in the newborn period. Although each of these 13 children was carefully evaluated, none

had signs of neurologic, ophthalmologic, or severe generalized disease at birth or at the time of diagnosis of congenital *T. gondii* infection; they would not have been detected if screening tests for antibodies to *T. gondii* had not been performed. (Data regarding earlier clinical and laboratory evaluations of eight of the children from Alabama had been reported previously) [328,865,870].

Group II consisted of 11 children in whom neither their parents nor their physicians detected signs of congenital infection during the newborn period. The diagnosis was entertained only after they had ophthalmologic or neurologic signs suggestive of congenital *T. gondii* infection. Because these children were preselected as a result of having developed complications of their initially subclinical infection, and because it is possible that a more detailed evaluation during the newborn period might have detected abnormalities in some of them, they were analyzed separately from the children in group I. The characteristics of both groups are shown in Table 31–39.

Of the 24 children, 11 (5 in group I and 6 in group II) never received treatment (See Table 31–49). Four children (1 in group I and 3 in group II) were given treatment only after adverse sequelae were noted or received treatment for less than 2 weeks, or both; for purposes of analysis, these children were referred to as “untreated.” Nine children (7 in group I and 2 in group II) were given treatment for at least 3 weeks before 1 year of age and before the development of neurologic or intellectual deficits. Treatment in all cases consisted of regimens of pyrimethamine and sulfadiazine or pyrimethamine and trisulfapyrimidines.

All children were evaluated at least once. The results of the study revealed that untoward sequelae of their congenital infection ultimately developed in 22 of the 24 children (92%). The two children in whom sequelae did not develop were in group I; they were 8 and 10 years of age at the time of last examination.

**Ophthalmologic Outcome.** In group I, sequelae developed in 11 of 13 children (85%), and chorioretinitis was the initial manifestation of disease in all 11 (Table 31–40). The age at onset of eye disease ranged from 1 month to 9.3 years of age, with a mean of 3.7 years of age. At their most recent examination, three children had unilateral functional blindness, and the remaining eight had

chorioretinitis without loss of visual function. Subsequent to the initial episode of chorioretinitis, 3 of these 11 children had one or more additional episodes of active chorioretinitis at ages ranging from 1 to 8.7 years. Although temporarily decreased visual function was associated with the recurrent episodes of active chorioretinitis in some of these children, no permanent, additional loss of visual function has resulted.

In group II, eight children initially presented with ocular abnormalities (see Table 31–40). The age at onset of eye disease ranged from 3 months to 1 year of age, with a mean of 0.4 years of age. The two other children in group II in whom ophthalmologic examinations were performed had chorioretinitis at the time they had neurologic abnormalities. At their most recent examination, five children had bilateral functional blindness, three had unilateral functional blindness, one had moderate unilateral visual loss, and one had chorioretinitis without loss of visual function. Subsequent to the initial episode of

chorioretinitis, two of these children had recurrences of active chorioretinitis at 2.3 to 3.5 years of age. One child in group II did not have an adequate ophthalmologic evaluation at the time of last follow-up examination and is not included in the results of ophthalmologic outcome.

**Neurologic Outcome.** Neurologic sequelae (Table 31–41) developed less frequently than did chorioretinitis and were always associated with eye pathology. Five (38.5%) of 13 children in group I suffered neurologic sequelae. Major neurologic sequelae developed in 1 (8%) and minor neurologic sequelae developed in 4 (31%) children in group I. Two of the 4 children with minor neurologic sequelae in group I had delayed psychomotor development during the first 6 months of life, but their subsequent psychomotor development and neurologic status were normal when they were last examined at 3.7 and 8.7 years of age, respectively. Eight (73%) of 11 children in group II suffered neurologic sequelae—major neurologic sequelae developed in 2, and minor neurologic sequelae developed in 3.

Of the 16 children from both groups I and II for whom skull roentgenograms during infancy were available, 5 (mean age, 5.2 months) had intracranial calcifications and 11 (mean age, 4.8 months) did not. One of these children had normal findings on skull roentgenograms in the first month of life, but calcifications were noted on repeat roentgenograms at 3 months of age. Intracranial calcifications were noted on initial roentgenograms obtained between 3 and 10 months of age in the remaining 4 children. Of these 16 children, major neurologic sequelae developed in 3 of 5 children with intracranial

calcifications and in 1 of 11 children without intracranial calcifications ($P$ = .06). No correlation was found between neurologic outcome and birth weight, race, or age at the most recent examination. In eight children in group I, cerebrospinal fluid examinations were performed during the newborn period. In 7 of the children, abnormalities were detected; such abnormalities did not correlate with the development of any type of sequelae.

**Intelligence Testing.** The results of intelligence testing are presented in Table 31–42. IQ scores correlated directly with upper socioeconomic class (r = 0.37, $P$ <.05). In addition, the 16 white children had a higher mean IQ (89.6 ± 26.3) than that of the 6 nonwhite children (81.2 ± 15), but this difference was not statistically significant. Two of the children in group I (one white, one African American) had moderately severe retardation (IQ scores of 36 and 62, respectively), as did two of the children (both white) in group II (IQ scores of 43 and 53). A tendency was identified for IQ scores to decrease on later testing among the seven children (six in group I and one in group II) who were tested more than once. The mean IQ score of these children fell from 96.9 to 74 over an average of 5.5 years, with all but one child showing a decrease on repeat testing.

No significant correlation was found between IQ scores and the finding of abnormal cerebrospinal fluid in the newborn period, intracranial calcifications on skull roentgenograms, age at time of testing, or birth weight below the tenth percentile. In fact, a trend toward higher IQ

scores (mean, 96.9) was identified in children with birth weight below the tenth percentile. These results of intelligence testing must be interpreted with caution. The range of IQ scores was wide, testing was performed by different persons, and different tests were employed.

**Hearing Impairment.** The incidence of sensorineural hearing loss in the study population also appeared to be excessive. In an earlier study in some of these children [865], the incidence of mild sensorineural hearing loss in 41 normal control children (mean age, 3.8 years) was 5%; no children with more severe sensorineural hearing loss were observed. In this study [361], the incidence of sensorineural hearing loss in children tested in group I was 30% and that in group II was 22%. One child in each group had moderate unilateral hearing loss.

**Special Considerations.** Because this study was not controlled and was only in part prospective, certain limitations must be considered in interpreting the data. Children in group II were detected because of the development of sequelae that were sufficiently significant to attract medical attention. Thus it would be inappropriate to use data from this group to determine the frequency of such sequelae among children born with subclinical infection. Nevertheless, data from group II do provide information regarding the potential seriousness of ocular disease in children born with subclinical congenital *T. gondii* infection and regarding the risk of subsequent neurologic sequelae in children in whom chorioretinitis developed previously. No data from this study or from other studies indicate that a significant bias toward more severe disease was introduced by the different screening methods employed in group I. It is likely, therefore, that the data from group I provide a reasonable estimate both of the seriousness and of the frequency of complications in children with initially subclinical congenital *T. gondii* infection. Because of the small sample size and the lack of a

matched control group, these data must, however, be considered estimates. Moreover, whether postnatal therapy was beneficial cannot be determined from this study.

## Paris Studies

Of 108 infants with congenital *T. gondii* infection who were diagnosed and evaluated prospectively by Couvreur and colleagues [364] and discussed by Szusterkac [871], 27 had chorioretinitis. In 26 of these infants, the lesions were present at the time of the first ophthalmoscopic examination after birth. In only one infant were findings on the eye examination normal at birth, with subsequent development of chorioretinitis. In three other infants, a retinal lesion was noted at the time of first examination, and a new lesion was discovered on follow-up examination. It is noteworthy that only 16 of the 108 infants were examined after the age of 2 years and only 3 were examined after the age of 5 years. Only 6 of these 19 children had chorioretinitis on initial examination. Of interest is the striking difference between the children who received treatment and those who did not during the first year of life. Among the children who received treatment, no lesions were discovered after the age of 2 years, whereas in 8% of the children given no treatment, chorioretinitis developed between 10 months and 4 years of age. It is possible to assume from the experience of Koppe and colleagues [245,360] and Wilson and coworkers [361] that careful follow-up evaluation in these 108 children would reveal additional cases of chorioretinitis and additional lesions in the 27 children who already had eye disease. Follow-up evaluation in such series is important because all of these children were identified prospectively and received treatment for approximately 1 year either from birth or from the time at which the diagnosis was established in the first months of life.

Additional data in children in whom congenital *T. gondii* infection was not recognized in the newborn period have been published by Briatte [872]. These data were obtained in collaboration with Couvreur, Hazemann, and Desmonts in Paris. Hazemann established a program at a number of medical centers in the Paris area in which any infant could be examined free of charge at the request of the mother. The first examination was performed when the infant was 10 months of age. Among the blood tests performed in this program was the dye test to detect cases of previously undiagnosed congenital *T. gondii* infection. Forty-eight infants with subclinical congenital *T. gondii* infection were detected among the 20,513 infants examined from 1971 through 1979. (The data were corrected for those cases in which the infection probably was acquired postnatally.) Infants with clinical toxoplasmosis probably were not examined in this program because these infants would already be under medical care, so that their mothers probably would not request their participation in this medical screening program. For the same reason, it is likely that the vast majority of infants screened had few or no problems during infancy.

The frequency of probable congenital *T. gondii* infection in the entire study population averaged 2.33 per 1000 (range, 0.38 to 5.2 per 1000 per study year). The frequency of chorioretinitis among the 48 infants is shown in Table 31–43. Of these 48 children (who, of course, did not receive treatment for their *T. gondii* infection during the first 10 months of life), chorioretinitis developed in 18% by the age of 4 years. In 8 of the children, chorioretinitis developed after the age of 10 months and before the age of 4 years. This latter finding differs considerably from that reported by Szusterkac [871] in infants who received treatment in the early weeks or months of life (see earlier discussion). Cerebral calcifications were present in 3 of the 48 infants previously unrecognized as having infection, which therefore had not been treated [872].

### Interpretation of Stanford-Alabama and Paris Studies

For proper interpretation of the data presented for the Stanford-Alabama study [361] and the study reported by Briatte [872], it is important to understand how the data might be biased because of the method of case selection. The method used in the studies in Alabama for detection of subclinical congenital infection (detection of an increase in cord serum IgM) might have selected for the most "severe" (heavily infected) cases among subclinically infected newborns. In the studies performed by the Stanford group, some of the patients were selected because manifestations of the infection occurred during infancy. Thus in both of these studies, the method of selection might have predisposed to an increased frequency of more severe cases in the Stanford-Alabama study. By contrast, in the study reported by Briatte, it is probable that the most "benign" cases were selected among subclinically infected newborns because the investigators studied infants who had few or no medical problems during the first 10 months of life. Despite this bias toward "mild" infection, 18% of the infants whom the Paris group observed had ocular lesions by the age of 4 years.

**TABLE 31–43** Frequency of Chorioretinitis in Infants with Subclinical Congenital *Toxoplasma* Infection First Discovered in a Systematic Serologic Screening Program

| Examined again at 4 yr | 28 | 8 | 1 | 9 (18) |

*Data adapted from patients studied by Drs. J Couvreur, JJ Hazemann, and G Desmonts. Cases are discussed by Briatte.*

### Amsterdam Study

As mentioned earlier, in 1964 a prospective study was started in Amsterdam to determine the frequency of congenital toxoplasmosis [360]. Of 1821 pregnancies screened, 249 infants were enrolled in the study—21 because of seroconversion in the dye test, 42 because of a high baseline dye test titer, 183 because of a slight rise in dye test titer, and 3 because their mothers had toxoplasmosis shortly before gestation. At birth, four infants had chorioretinitis and parasites were isolated from placenta and cerebrospinal fluid of one other infant. Each of these five children received pharmacologic treatment. Seven children who were asymptomatic and whose dye test titer did not revert to negative received no treatment. Ten other questionably infected children who had no symptoms but whose dye test titer became negative 18 months after birth also received no treatment. These 22 children were evaluated annually for 5 years by physical examinations and dye and CF tests. No new abnormalities were detected, except in one patient with chorioretinitis, who required surgery to correct a squint at the age of 2 years [360]. The 12 congenitally infected children continued to be examined yearly until the age of 20 years.

The authors' original optimistic view was revised in their 1986 publication [190]. One of the five children who received treatment and one of the symptom-free children had new scars in their eyes at the age of 6 years. Additional new scars or acute lesions were observed in both the "treatment" and "no treatment" groups of children. In three children, scars appeared at ages 11, 12, and 13 years, respectively. One patient had a new scar in his right eye when examined for the first time at age 17, and another had no severe eye abnormalities until the age of 18 years, when an acute lesion appeared in the right macula that led to blindness in that eye. Another patient had a new acute lesion in her right eye at the age of 12 years and again in both eyes at the age of 13 years. Thus after a total of 20 years of follow-up, of 11 congenitally infected children, 9 had scars in one or both eyes. Four of these children had severely impaired vision in one eye, and three were blind in one eye. Among the 10 questionably infected children, 1 had a scar in the right macula at 5 years of age that led to severe visual impairment. Another child whose mother had toxoplasmosis during gestation remained persistently seropositive. He had not developed any scars in his eyes. The other eight children remained seronegative for 5 to 19 years, and some acquired toxoplasmosis during this time. The 11 congenitally infected children did not differ from controls in their school performance. None of the 11 was mentally retarded.

From the results of this prospective study, it is apparent that 9 of 11 children (82%) after 20 years of follow-up had significant sequelae of toxoplasmosis, and that 5 of these 11 had severely impaired vision (Fig. 31–36). Although the report by Wilson and associates described earlier demonstrated a similar percentage of untoward sequelae by the age of 10 years, theirs was not a prospective study [361].

### U.S. National Collaborative Chicago-based Treatment Trial Study

A national, prospective study, the NCCCTS, is being carried out by a group of investigators based in Chicago (telephone number 773-834-4152/773-834-4131). This study is evaluating long-term outcome for infants given pyrimethamine (comparing two doses) in combination with leucovorin and sulfadiazine (100 mg/kg per day in two divided doses). Medications are begun when a child is younger than 2.5 months of age according to the method shown in Figure 31–34 and continued for 12 months. Therapy is monitored by parents with a nurse case manager and the primary physician, and compliance also has been documented with measurement of serum pyrimethamine levels. Children who have not received treatment during the first year of life and are referred to the study group when they are older than 1 year of age also are included in the study. Patients are evaluated comprehensively by the study group near the time of birth and at 1, 3.5, 5, 7.5, 10, and at 5-year intervals thereafter. The following parameters are evaluated: history; physical status; audiologic, ophthalmologic, neurologic, and cognitive function; and development; a number of other variables are measured by laboratory tests, including tests of hematologic status and serologic and lymphocyte response to *T. gondii* antigens, and neuroradiologic studies.

This ongoing study of the treatment of infants began in 1981. It continues to the present time and has provided an opportunity to determine and compare the manifestations, natural history, and outcomes in children with congenital toxoplasmosis who were treated with either one or another regimen.

This study began with a phase 1 clinical trial, which was conducted from 1981 to 1991. This phase demonstrated that it was feasible and safe to administer pyrimethamine and sulfadiazine to infants throughout the first year of life. Medicine preparation and administration were as shown in Figure 31–34 and Tables 31–33 and 31–34. Pharmacokinetics of pyrimethamine in infants were characterized. Twelve children took the recommended dosage of pyrimethamine and two children took a higher dose.

During phase 1, and in the subsequent phase that is still ongoing, many of the infants had severe involvement at the time of enrollment. The findings at presentation in infants in the NCCCTS were comparable to those in

infants described by Eichenwald [356] at presentation. However, in contrast to the Eichenwald study for the children with severe involvement and the earlier Wilson and colleagues [604] study for those with milder involvement, outcomes were remarkably different when these children were evaluated at 1 to 10 years of life. There was no hearing loss. And, in contrast to the severe cognitive impairment, frequent motor impairments, seizures, and visual loss that often progressed in association with recurrent episodes of active chorioretinitis, most of the children were ambulatory without motor deficits. They were functioning normally in their families and school settings, without seizures, and without progression of their retinal disease, which often was already substantial at birth. These outcomes appeared to be considerably better than those described in any previously published study of comparable children who had been untreated or treated for only one month.

Based on these findings, demonstration of achievable blood levels of pyrimethamine, and documentation that these treatment regimens could be safely administered, a placebo controlled trial was considered as a next phase. However, after reviewing these data in 1990, the investigators and the Ethics (Institutional Review Boards and National Institutes of Health panels) and Data Safety Monitoring Boards, concluded that the outcomes for the children in the phase 1 study were markedly improved relative to all prior studies of comparably ill children. Based on this conclusion, a prospective, randomized, controlled efficacy trial with prespecified endpoints/outcomes of treatment was initiated with one group receiving a higher and the other group receiving a lower dose of pyrimethamine; the doses selected were those two doses that had been found to be safe in the initial 10 years of the phase 1 trial. This study has been criticized by some because there is no placebo control group, despite the fact that this group was not included because of the recommendations of the ethics boards. This is also a study of referred patients who choose to participate, which is a limitation of the design of this and most clinical trials. This reflects the lack of a systematic, standardized, mandated, or uniformly implemented serologic screening program for pregnant women and infants in the United States, in contrast to the program in place in France.

In this study, pyrimethamine has been administered with leucovorin and sulfadiazine to infants who are treated throughout their first year of life (Figure 31–34) [878]. Endpoints for outcomes were prespecified and based on a careful analysis of the literature and the phase 1 trial experience. Sample sizes were selected based on the predicted frequency of outcomes based on the earlier literature to be sufficient to detect significant differences in outcomes with the two treatment regimens with a beta error of 80%.

These two treatment regimes were not selected to be treatments that were widely disparate, with one expected to fail and one to succeed. Rather, they were based on two treatments that had been found to be feasible, safe, and that produced potentially therapeutic serum and CSF levels of pyrimethamine in the phase I trial. The underlying assumption was that there might be a dose-related effect for efficacy or safety but, even if there were no differences in outcomes between the two treatment groups, if the improved outcomes observed in the phase 1 study compared to the outcomes described in the earlier literature were also present for the larger number of children in this randomized phase of the study, benefit and efficacy of treatment would be further supported by this comparative efficacy trial.

Infants are stratified on the basis of severity of disease at their first visit to the Chicago Center into the following categories: no disease, mild involvement, generalized disease, moderate or severe neurologic disease, with or without retinal disease, and with or without prenatal treatment. Children who were evaluated in the first two and a half months of life in Chicago were placed into these stratification categories and randomized to receive the higher or lower dose of pyrimethamine. This study has been supported by the U.S. National Institutes of Health and by donations of free transportation from airlines, which have allowed the evaluations to be performed by a single group of experienced observers, in a consistent, careful, and thoroughly documented manner. The periodic analyses of the data have provided information about the natural history of the treated infection in a detailed, rigorous, and consistent manner. Information has also been obtained regarding early or late side effects or toxicities of the medicines used, and the appearance of delayed sequelae. In the early phase, it was clear that this follow-up was important, since serologic test results after stopping the medicines showed a rebound in antibody titers specific to *T. gondii*, which suggested that bradyzoites were not eliminated by treatment and treated children therefore remained at risk for recrudescence of this disease.

During the 19 years since this randomized study was initiated, there have been some years in which the research grant support needed to bring children to Chicago for randomization and evaluation was not available. During those times, children were considered to be part of the feasibility/observational cohort and were evaluated as soon as research support was restored and travel to Chicago was possible. If infants could not be evaluated in Chicago by the time they had received 2.5 months of treatment, they were not randomized and were treated with the higher dose of pyrimethamine. Data for the randomized and observational cohorts have been analyzed separately and considered together throughout the study, and have been found to be comparable when reviewed by the Data Safety Monitoring Board each year. The prespecified enrollment targets for the severe stratification categories were met in 2008 and only those children who are in the no disease or mild categories are still randomized. All children in the moderate or severe categories now are treated with the higher dose of pyrimethamine.

Results for the period between 1981 and 2004 were reported in 2006 [878]. Outcomes, with comparisons between the lower and higher dosage and comparisons with data from earlier studies in which children were either untreated or treated for 1 month, are in Tables 31–18, 31–44, 31–45, 31–46, 31–48, 31–49.

In summary: Manifestations of active infection resolved in association with treatment [433,773,877–878]. Outcomes were markedly improved in this cohort relative to

**Historical patients were patients who received no treatment and were diagnosed after 1 year of age. In the treatment groups, children received 2 months (Treatment A) or 6 months (Treatment C) of daily pyrimethamine and sulfadiazine, followed by pyrimethamine on Monday, Wednesday, and Friday and continued daily sulfadiazine for the remainder of the year of therapy.*

those in children who were untreated or treated for 1 month with comparable severity at presentation. There was no sensorineural hearing loss (See Table 31–18). The incidence of recurrent eye lesions was approximately 10% into early adolescent years for those with no or mild symptoms at birth and approximately 30% for those with moderate or severe disease at birth. Cognitive and motor function was in the broad range of normal for 100% of the children categorized as having no or mild disease. Cognitive and motor functions were in the broad range of normal for 73% and 80% of the children in the moderate and severe categories, respectively. There were no statistically significant differences in efficacy or toxicity between the treatment regimens (See Table 31– 47). The only substantial manifestation of toxicity was transient neutropenia, which responded to increased dosages of leucovorin or withholding of pyrimethamine (See Table 31–47). This appeared to occur primarily during the prodrome of concomitant viral infections. Dental caries occurred in one of the first children studied.

*Children received 2 months (Treatment A) or 6 months (Treatment C) of daily pyrimethamine and sulfadiazine, followed by pyrimethamine on Monday, Wednesday, and Friday and continued daily sulfadiazine for the remainder of the year of therapy. Feasibility group patients received treatment in the early phase of the study before randomized study. Toxicity for Treatments A and C was measured as episodes of reversible neutropenia requiring temporary withholding of medications.

Thereafter, parents were cautioned to clean teeth of older infants because medications were administered in sugar suspensions. Pediatricians were cautioned to avoid using a second sulfonamide to treat concomitant infections such as otitis media because more prolonged neutropenia occurred in one child in conjunction with such therapy. There have been no late malignancies or hematologic dyscrasias in those who were treated [878].

These findings are similar to those reported in this NCCTS cohort at earlier times and in other studies in which children were treated in this manner.* Although the children in the NCCCTS study are largely children with moderate or severe disease [878], these outcomes

are considerably more favorable than those described for comparable children who were untreated or treated for shorter times in other studies.

All signs of active infection (i.e., thrombocytopenia, hepatitis, rash, meningitis, hypoglycorrhachia, active chorioretinitis, vitritis) resolved within weeks of initiation of therapy [773]. Chorioretinitis did not progress or relapse during therapy.

Audiologic outcome was significantly better than that reported in the earlier literature (see Table 31–18) [486]. To the present time, no sensorineural hearing loss was noted in the 139 children who received treatment, in contrast with a 14% incidence of "deafness" [356] or 26% incidence of "hearing loss [361]" in earlier studies. Comparisons of outcomes in this and earlier studies are summarized in Table 31–18 (see also the next section, "Comparison of Outcomes").

Retinal disease became quiescent with therapy within weeks, with no recrudescence observed during therapy [773]. To the present time, new lesions (primarily those "satelliting" pre-existing lesions) occurred in older children. The oldest child who received treatment was 28 years in 2009. Lesions also occurred in previously normal-appearing retinae. These were noted first at study evaluations at 3.5, 5, or 7.5 years of age and had not been present at the preceding evaluation. To date, no loss in visual acuity has occurred when prompt treatment of active recurrent chorioretinitis was initiated. Comparison of early outcomes with 2 versus 6 months of 1 mg/kg/day of pyrimethamine, followed by this dosage administered on Monday, Wednesday, and Friday, both administered with sulfadiazine and leucovorin, is shown in Table 31–46. At present, no statistically significant differences have been noted. Thus treatment during the first year of life with pyrimethamine and sulfonamides, unfortunately, did not uniformly prevent recrudescent chorioretinitis. Determination of whether it reduces the incidence of recurrent or new chorioretinitis, compared with the almost uniform occurrence of this complication in children who did not receive treatment, who were diagnosed in earlier decades, requires longer follow-up evaluation of more children. It is especially important to try to determine whether treatment prevents subsequent chorioretinitis when no retinal lesions are present at birth.

Visual acuity that is adequate for all usual activities and reading has been noted in some children with large macular scars. Nonetheless, impairment of vision has been one of the two most prominent sequelae (Table 31–48).

Visual impairment has presented a challenge in the care of children of school age; that is, special attention is needed to optimize their ability to read, and participation in learning activities must be ensured so that their visual impairments do not impair cognitive development. Retinal scars have been central, peripheral, unilateral, and bilateral in location and have resulted in partial and complete retinal detachment. Loss of sight at presentation (e.g., due to retinal detachment) usually has been associated with the most profound neurologic impairment. Visual outcomes to date are contrasted with those of earlier studies in the next section: "Comparison of Outcomes." Neurologic and cognitive function of most of these treated children has been significantly better than reported in earlier decades [433,873–875]. This is summarized in Table 31–49.

In the earlier report by Eichenwald [356], more than 80% of children who had substantial generalized and neurologic involvement at birth and who received no treatment or whose treatment was for 1 month had IQ scores below 70 at 4 years of age. In that report, initial involvement in the perinatal period appears to have been less severe or similar in severity to that of children in the NCCCTS. In contrast with the outcome in that earlier series, only 31% of the treated children who had substantial generalized or neurologic manifestations of infection or both in the perinatal period and who received treatment between 1982 and September 2008 in the NCCCTS had substantial cognitive impairments. The remaining 69% of the treated children in the NCCCTS who had substantial generalized or neurologic manifestations of infection or both in the perinatal period have to date demonstrated normal development and are likely to be capable of self-care. The relative contribution of shunt placement, antimicrobial therapy, and adjunctive supportive care to this improved outcome cannot be determined with certainty. The observation that almost all children without hydrocephalus in the NCCCTS have at least average cognitive function contrasts dramatically with the 81% incidence rate of mental retardation at 4 years of age in children having generalized disease in Eichenwald's series and who received no treatment or whose treatment was for 1 month [356]. This difference suggests that antimicrobial therapy may contribute significantly to the more favorable outcome. No deterioration of cognitive function has occurred over time in these children who received treatment, although visual impairment clearly has affected school performance and ability to acquire information and skills for some children [873]. This finding contrasts with earlier reports of diminished cognitive function over time for children not given treatment or those whose duration of treatment was less than 1 month who had subclinical disease in the perinatal period (described by Wilson and associates) [361]. Despite the remarkably good cognitive outcome for many of these children, the impact of the infection on their cognitive function is reflected in the fact that their IQ scores often are 15 points less than those of their nearest-age siblings ($P < .05$) [873].

Factors in the newborn period that often were associated with poorer prognosis in the NCCCTS study included apnea and bradycardia, hypoxia, hypotension, delays in shunt placement and/or initiation of therapy, inability to perceive light retinal detachment, cerebrospinal fluid protein concentration greater than 1 g/dL, diabetes insipidus in the perinatal period, hypsarrhythmia, and markedly diminished size of the brain cortical mantle that did not increase after shunt placement [872]. Nevertheless, favorable outcomes also have been noted when some of these abnormalities were present [872,873,876].

The experiences in the NCCCTS (see Figures 31-13 through 31-15) indicate that initial appearance of the brain on CT scan is not necessarily predictive of poor outcomes. Therefore these investigators have approached this disease in infancy as one in which all aspects of care should be optimized because even when factors more frequently associated with adverse outcomes are present, adverse outcomes do not always occur.

It has been possible to discontinue antiepileptic medications in some infants who have had seizures (presumably due to active encephalitis) in the perinatal period, without recurrence of seizures. New-onset seizures have developed in a small number of treated children after the perinatal period. Hypsarrhythmia occurred in two children. One of these latter children responded dramatically and promptly to adrenocorticotropic hormone injections (pyrimethamine and sulfadiazine were administered concomitantly), and one responded to clonazepam treatment.

In many instances, a number of considerations may make it reasonable to withhold antiepileptic therapy after a short course of such medications. These considerations include the potential adverse interactions of many of the antiepileptic medications with the antimicrobial agents needed to treat *T. gondii* infection [877]. If antimicrobial therapy results in resolution of active encephalitis, which was the seizure focus, antiepileptic medications would no longer be needed. In the NCCCTS, a lack of recurrence of seizures when antiepileptic medications were discontinued in a number of cases [789,873,875] supports this approach. Levetiracetam has been used successfully for treatment of seizures and does not have the effect of inducing enzymes that degrade pyrimethamine as phenobarbital does and does not have the effect of displacing sulfonamides from albumin as does phenytoin.

**Comparison of Outcomes.** A comparison of the outcomes observed in the NCCCTS and in previous studies and their relationship to treatment is shown in Tables 31–45 and 31–49. Early treatment in the NCCCTS appeared to result in more favorable outcomes than were reported to occur for untreated infants or infants who received treatment for only 1 month [217,877–879]. This was the case although the severity of neurologic disease at birth in the NCCCTS was comparable to or greater than in those reported by Eichenwald and colleagues [356] in the same stratified disease categories.

Analysis of the full cohort is presently ongoing (McLeod R, unpublished). As of October 2008, 149 children who received treatment have been evaluated. Ages ranged from newborn to 26.8 years (mean age, 13.1 years). Forty-two historical (no treatment) patients also are being followed. They range in age from 5.8 to 61.8 years of age (mean age, 24.6 years). Outcomes appear to be similar to those reported in 2006 [878]; higher and lower dose regimens have remained similar in toxicity and in early outcomes

for pre-established endpoints and active disease has continued to become quiescent with treatment. Enrollment in the NCCCTS is currently ongoing. Infants can be enrolled by phoning 773-834-4152 or 773-834-4131.

**Current State of Knowledge Regarding the Effects of Postnatal Treatment on Outcome.** Our review of available data and the experience presented above suggests that early postnatal treatment of infected infants improves long-term outcomes. We recognize that the current data suggesting benefit are not based on placebo-controlled clinical trials. Some argue that for this reason, despite the favorable results shown in other contexts, placebo-controlled studies are still needed to demonstrate efficacy [195,880]. Although we agree that such studies would be necessary to provide incontrovertible proof of efficacy, lack of evidence for benefit from placebo-controlled trials is not evidence that postnatal treatment is of no benefit. For this reason, until such placebo-controlled data with long-term follow-up and analyses as careful as those in the NCCCTS become available, we and others [196] continue to recommend that treatment be given following the regimens described for the NCCCTS study. Ideally, in the United States and Canada, when physicians feel this may be of benefit for their patients and in understanding the natural history of this disease, consideration should be given to referring cases to the NCCCTS.

**Ophthalmologic Outcome in Children in the United States NCCCTS Study.** In the NCCCTS study, recurrent toxoplasmic chorioretinitis was commonly observed in persons with apparent or proved congenital infection that was not treated in the perinatal period and during the first year of life [883,884]. Twenty-eight children were considered to have congenital *Toxoplasma* infection based on the presence of seropositivity by 24 months of age alone or in concert with central nervous system calcifications, hydrocephalus, or other clinical signs compatible with congenital *Toxoplasma* infection. However these children were not diagnosed in the first year of life and were therefore not treated; of these 28, 25 have returned for follow-up. Of these 25 patients with follow-up, 18 (72%) developed at least one new ocular lesion by the time of their most recent examination at 10.9 ± 5. 7 years of age, 7 (39%) had new lesions bilaterally, and 13 (52%) had new central lesions [884].

It is critical to note that the children who were untreated, although they presented with more mild disease and had more recurrent eye disease than occurred in those who were treated, are clearly a distinct group. They may not be comparable for many different reasons to those who were treated. Nonetheless, it is interesting to contrast the outcomes of children who were treated in the NCCCTS with those who were untreated. Of the 132 children who were diagnosed and treated in the first year of life or in utero and in the first year of life, and who were last examined at 10.8 ± 5.1 years of age, 108 returned for follow-up. Of the 108 followed-up patients, 34 (31%) developed at least one new ocular lesion, 13 (12%) had bilateral lesions, and 15 (14%) had new central lesions [883]. Development of new eye lesions and active chorioretinitis appeared to be more common around 5 to 7 years of age and in adolescence. In a substantial number from both groups, new lesions became evident when they were 10 years of age or older, which indicates that long-term follow-up is important in assessing the efficacy of treatment given in early life.

This pattern of late recurrence in congenital toxoplasmic chorioretinitis is interesting in the context of recent observations in the Netherlands [885]. This is a study of a cohort of 153 persons, 11 of whom had congenital toxoplasmosis, and 82 of whom had ocular toxoplasmosis, which could not be categorized as either congenital or postnatally acquired. Specific treatment for episodes of recurrence and criteria for discontinuing treatment were not specified. In this study, 323 episodes of recurrence in first-affected eyes were detected in individuals followed-up from 0.3 to 41 years. Recurrence risk was greatest immediately following an episode and decreased with increasing disease-free intervals; recurrences often occurred in clusters. Relative risk of recurrence declined 72% with each 10-year interval after the first episode and declined 15% with each 10-year increase in age at the first episode. Patients more than 40 years of age were at higher risk of recurrence than younger patients. For the treated persons in the NCCCTS cohort, symptomatic recurrences have been relatively uncommon (878) and these have not occurred in clusters. For the persons not treated in their first year of life in the NCCCTS, there have been teenagers who had multiple recurrences prior to treatment and no further recurrences following treatment of the recurrence and then administration of suppressive medicine.

**Treatment of Relapsing Chorioretinitis.** The factors that lead to relapse of chorioretinitis are not known. An antimicrobial agent that eliminates encysted organisms in the eye is needed because it is clear that treatment with currently available antimicrobial agents does not uniformly prevent or eliminate relapsing chorioretinitis [433,881]. Longer follow-up of large numbers of treated infants (especially those who acquired their infection in the third trimester and have no retinal involvement at birth) is needed to determine whether treatment reduces the frequency of this sequela. After treatment during the first year of life, congenitally infected infants and young children remain at risk for relapse; for this reason, we and many other authorities currently recommend that they undergo ophthalmoscopy at 3- to 4-month intervals until they can reliably report visual symptoms. Studies are ongoing to determine whether continued frequent follow-up ophthalmologic evaluations and earlier treatment can prevent the devastating consequences of recurrent chorioretinitis. Careful evaluation, including retinal examination, should be performed whenever ocular symptoms suggestive of active chorioretinitis are present.

In infants and in the limited number of older children followed to date in the NCCCTS, active chorioretinitis appeared to resolve within 1 to 2 weeks of beginning treatment with pyrimethamine and sulfonamides as described in Table 31–33. Occasionally, particularly with relatively longer delays in initiating treatment, resolution of active lesions and vitritis was more prolonged. With recurrence of lesions after the first year of life, antimicrobial treatment has been continued 1 to 2 weeks beyond resolution of signs and symptoms. It is standard practice to administer prednisone (1 mg/kg daily in two divided doses [Table 31–33]) in conjunction with pyrimethamine

and sulfonamides if inflammation threatens the macula, optic disk, or optic nerve. The efficacy of this practice is unknown. Some investigators have recommended clindamycin or tetracycline therapy [882]. No convincing data are available to allow determination of whether inclusion of these latter two medications would be beneficial.

In a randomized trial in Brazil that included 124 patients ranging in age from 7 to 53 years, prophylaxis with TMP/SMX in a dose of 160 mg/800 mg) given every 3 days for up to 20 months reduced the incidence of recurrent eye lesions from 23.8% (i.e., in 15 patients who received no treatment) to 6.6% (in 4 patients who received treatment) [209]. However, the high incidence of allergy to sulfonamides (25%) makes their use for prophylaxis a potential problem. If allergic reactions develop, treatment of active eye disease that occurs later may require use of other antimicrobials. A recent study demonstrates prevention of recurrences with intravitreal clindamycin (1.5 mg/0.1 ml) and dexamethasone (400 microgram/0.1 ml). Treatment was given weekly or every 4 weeks for pregnant patients and was associated with resolution of toxoplasmic retinochoroiditis (Lasave, et al, Ophthalmology, 2010).

Because transmission occurs frequently when acute infection is acquired in the latter part of the third trimester, we consider it reasonable to provide treatment for the fetus by administering pyrimethamine and sulfadiazine to the recently infected mother. A diagnostic procedure to detect infection in the fetus (see previous on "Prenatal Diagnosis of Fetal *Toxoplasma gondii* Infection") should be performed before this therapy is instituted because such treatment may obscure the diagnosis at birth. In such instances, decision making concerning treatment for the infant during the first year of life is significantly complicated by the lack of accurate diagnostic information.

When choroidal neovascular membranes have developed in the context of toxoplasmic chorioretinitis [410], especially with retinal hemorrhage, treatment with antibody to vascular endothelial growth factor has been curative. Such treatment has been used in infants and children.

**Ophthalmologic Outcomes after Prenatal Followed by Postnatal Treatment of Congenital Toxoplasmosis.** In a collaborative study by investigators in the United States (NCCCTS) and France, Brezin and colleagues [886] studied ophthalmologic outcome following treatment of congenital toxoplasmosis in utero and in the first year of life with pyrimethamine plus sulfadiazine and leucovorin. Ophthalmologic examinations were performed in 18 children born to mothers infected before 25 weeks of gestation. Both eyes were normal in 11 of the 18 children (61%) (mean age 4.5 years; range, 1 to 11). Only peripheral retinal disease was present in two children (both eyes in each). Four children had posterior pole scars in one eye; each of these four had normal visual acuity, and two of these four had peripheral retinal scars. The outcome was favorable for all but one child, in whom visual acuity was decreased and extensive, bilateral macular and peripheral lesions were present. In a similar, recent study in France [915], outcomes again were very favorable and shorter intervals between diagnosis and initiation of treatment were associated with improved visual outcomes.

These favorable results in France, especially the absence of central chorioretinitis, contrast markedly with the high prevalence of macular disease in the NCCCTS present at birth. The improved outcomes most likely reflect prenatal treatment of the French children. These French outcomes, including those of the Parisian center, suggest that a delay of > 8 weeks between maternal seroconversion and beginning of treatment is a risk factor for retinochoroiditis detected during the first two years of life in infants with treated congenital toxoplasmosis [915].

**Prospective Ophthalmologic Follow-up Evaluation of a Cohort of Congenitally Infected Infants in Lyon, France.** In an observational, prospective cohort study performed in Lyon, France by Binquet and her colleagues [766,887], maternal infections were identified through monthly testing of susceptible women. Most mothers became infected during the second trimester (89 [20%]) or third trimester (219 [68%]). Two hundred seventy-two (84%) were treated during pregnancy: 149 (46%) with spiramycin alone, 104 (32%) with spiramycin followed by pyrimethamine plus sulfadiazine, and 19 (6%) with pyrimethamine plus sulfadiazine. Treatment for the infant included a brief course (3 weeks) of pyrimethamine plus sulfadiazine followed by 1 year of treatment with Fansidar. In this cohort of 327 children (median duration of follow-up from birth was 6 years [interquartile range, 3 to 10], range, 6 months to 14 years), they [766] found that during a median follow-up period of 6 years, 79 (24%) had at least one retinochoroidal lesion, but bilateral visual impairment was not noted. Children who were diagnosed prenatally or at birth (rather than by an increase in specific IgG between 1 and 12 months of life), who had nonocular manifestations at the time of diagnosis, and who were premature had the highest likelihood of developing ophthalmologic manifestations. Thirteen (17%) of the 79 children had inactive lesions. The authors raise the possibility that the ophthalmologist may have observed those children with extraocular signs more closely. It also is possible that as examinations became easier with the increasing age of the children, more lesions that may have been easier to visualize were detected.

These same investigators recently reported that in this same cohort during a median follow-up period of 6 years after birth (interquartile range, 3 to 10 years), 238 (76%) of the 327 children (range, 6 months to 14 years) were free of any eye lesions. Sixty (18%) had no sequelae except for retinochoroiditis; 33 (11%) had at least one clinical sign of the infection (brain calcifications in 31, hydrocephalus in 6, microcephalus in 1). It is remarkable that in this cohort of 327 children, only 14 (4.3%) of 327 had visual impairment in one eye and none had bilateral visual impairment with a median follow-up of 6 years. Only 5 (1.5%) of 327 had neurologic symptoms. Thus, only 19 (5.8%) of 327 had apparent functional impairment due to congenital infection. Of the six with hydrocephalus, three had moderate psychomotor retardation, and two with calcifications had a single seizure. The investigators also reported that more than one lesion in the retina of the eye was predictive for involvement of the other eye. No association was found between new manifestations of infection and the age at which the initial

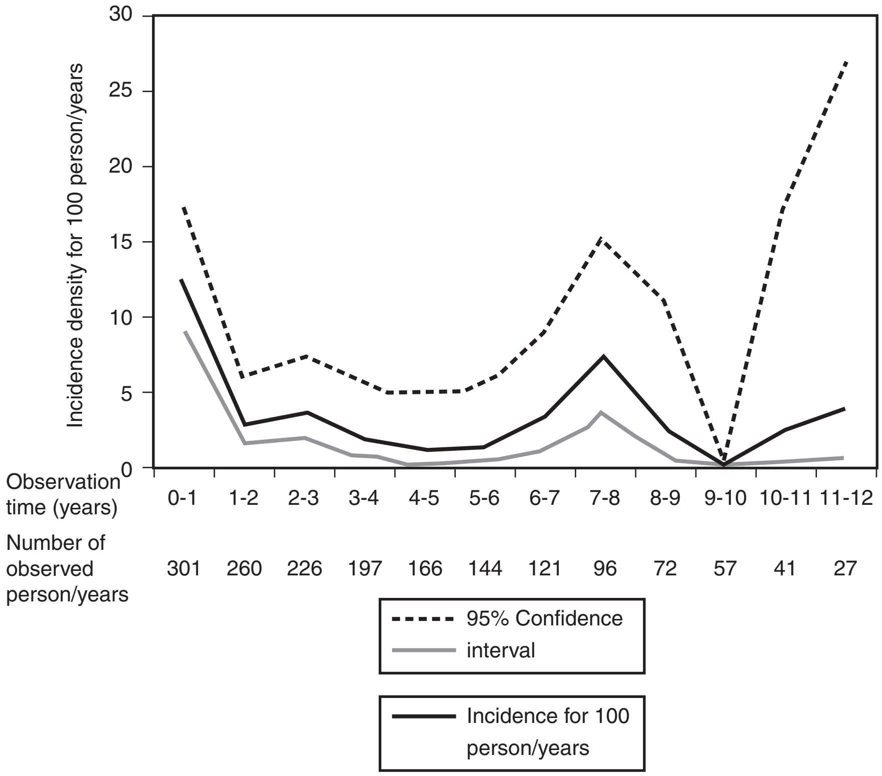

**FIGURE 31–37** Incidence density of first ocular lesion after diagnosis of congenital toxoplasmosis in a cohort of children described by Wallon and coworkers. *(From Wallon M, et al. Long-term ocular prognosis in 327 children with congenital toxoplasmosis. Pediatrics 113:1567–1572, 2004.)*

lesion was detected, activity of retinal disease, or locations of retinal lesions [766]. Figure 31–37 shows the times at which the investigators noted new lesions [766].

## PREVENTION

Congenital toxoplasmosis is a preventable disease. It is therefore the responsibility of health professionals who provide care for pregnant women to educate them on how they can prevent themselves from becoming infected (and thereby not place their fetus at risk). Lack of adoption of a systematic serologic screening program in the United States leaves primary prevention through education as the principal means of preventing this tragic disease. As a substantial proportion of infections are not associated with recognized risk factors, education concerning risk factors cannot eliminate the majority of infections. Nonetheless, a number of European studies suggest that educational materials can contribute to lowering numbers of infections and disease burden.

Seronegative pregnant women and immunodeficient patients are two populations in which avoidance of infection by *T. gondii* is most important. We consider that the data on morbidity, incidence, and cost of congenital toxoplasmosis warrant a major attempt to define and initiate means whereby congenital toxoplasmosis can be prevented [100]. Several methods for the prevention of congenital toxoplasmosis have been proposed. Attention to the specific hygienic measures outlined in Table 31–50 is the only method available for the primary prevention of congenital toxoplasmosis [181]. It is the responsibility of all physicians caring for pregnant women and women attempting to conceive (women at risk) to inform them of these preventive measures so that they will not place their fetuses at risk. The impact of these measures on the incidence of acquired toxoplasmosis in a given population has been discussed earlier, in the "Epidemiology" section. A substantial effort to educate women at risk

**TABLE 31–50** Methods for Prevention of Congenital Toxoplasmosis

| ***Prevention of Infection in Pregnant Women*** |
|---|
| Women should take these precautions:<br>1. Cook meat to well done.<br>2. Avoid touching mucous membranes of mouth and eyes while handling raw meat. Wash hands thoroughly after handling raw meat.<br>3. Wash kitchen surfaces that come into contact with raw meat.<br>4. Wash fruits and vegetables before consumption.<br>5. Prevent access of flies, cockroaches, and so on to fruits and vegetables.<br>6. Avoid contact with materials that are potentially contaminated with cat feces (e.g., cat litter boxes) or wear gloves when handling such materials or when gardening.<br>7. Disinfect cat litter box for 5 minutes with nearly boiling water. |
| ***Prevention of Infection in Fetuses*** |
| 1. Identify women at risk by serologic testing.<br>2. Treat during pregnancy, which results in an approximate 60% reduction in acquisition of infection among infants and a marked diminution in illness in the fetus and infant. |

*Adapted from Wilson CB, Remington JS. What can be done to prevent congenital toxoplasmosis? Am J Obstet Gynecol 138:357–363, 1980, with permission.*

and the physicians who care for them is clearly an important aspect of any program for prevention [888–890]. Educational materials that indicate how infection can be avoided should be provided in written form, in different languages appropriate to the population, and integrated into existing prenatal programs, visits and classes [199]. For a cost-benefit analysis of preventive measures for congenital toxoplasmosis in the United States, the reader is referred to the article by Roberts and Frenkel [891]. Additional studies to test effectiveness of specific educational measures in different contexts may be useful [892].

In addition to primary preventive measures, it is necessary to identify those women who acquire the infection during pregnancy (so that treatment during gestation, or abortion, can be considered). A mechanism for identification of these women also must be a part of any program for prevention of congenital toxoplasmosis. Because approximately 90% of women infected during pregnancy have no clinical illness and because there are no pathognomonic clinical signs of the infection in the adult, diagnosis in the pregnant woman must be made by serologic methods. This approach also is supported by the observation that only approximately 50% of mothers of congenitally infected infants in a recent series could recognize known risk factors or compatible clinical illness [893]. This makes prospective testing desirable.

## FOOD

The tissue cyst can be rendered noninfective by heating meat thoroughly to 66° C (150º F) or by having it smoked or cured. Curing may not eliminate the organism [46]. Freezing meat is a less reliable method of killing the cyst [46]; freezing meat at −20° C for 24 hours may be sufficient to destroy the tissue cyst [30], but not all freezers available in the United States can maintain this temperature even when new. To minimize the chance of infection resulting from handling raw meat, the hands should be thoroughly washed with soap and water after contact with the meat, and the mucous membranes of the mouth and eyes should not be touched with potentially contaminated hands while meat is handled. Eggs should not be eaten raw. Vegetables and fruits should be washed before they are eaten.

### Oocysts and Cats

To avoid infection by oocysts, several measures can be suggested. Cat feces may be disposed of daily by burning or flushing down the toilet, and the empty litter pan may be made free of viable oocysts by pouring nearly boiling water into it (an exposure time of 5 minutes is sufficient) [894]. Strong ammonia (7%) also kills oocysts, but contact for at least 3 hours is necessary. Drying, disposing as part of ordinary garbage, surface burial, freezing, or using chlorine bleach, dilute ammonia, quaternary ammonium compounds, or any general disinfectant cannot be relied on [895]. Women who are seronegative during pregnancy and immunodeficient persons should avoid contact with cat feces altogether. For handling litter boxes or working in sand or soil that may have been contaminated by cat feces, disposable gloves should be worn. Because sandboxes often are used by cats as litter boxes, a cover should be placed over the sandbox when it is not in use, and the hands should be washed after exposure to the sand. Flies, cockroaches, and probably other coprophagic animals serve as transport hosts for *T. gondii* and should be controlled and their access to food prevented [11]. Fruits and vegetables may have oocysts on their surfaces and should be washed before ingestion. Because the cat is the only animal known to produce the oocyst form, efforts should be directed toward preventing infection in cats. Feeding them dried, canned, or cooked food, rather than allowing them to depend on hunting (e.g., for birds and mice) as their source of food, reduces the likelihood of their becoming infected. Frozen raw meat also should be avoided because freezing may not always eliminate *T. gondii* [895].

Although it has been recommended that pet cats should be banished for the duration of pregnancy [896,897], this measure is hardly feasible and not necessary under most circumstances. Repeated requests for serologic testing of cats are being received by veterinarians in the United States, and in many instances, serologic test results are misinterpreted in respect to the danger of transmission. Patients are being misguided, unnecessary anxiety is being produced, and cats are being sacrificed without good reason. The fact is that cats with antibodies are safer pets than cats without antibodies because the presence of antibodies offers some degree of immunity to reinfection and thereby prevents or markedly decreases repetition of oocyst discharge [11]. Antibody determinations are not practical for the determination of infectivity of cats because the infectious oocysts usually are discharged before the development of antibodies in the animal [246,898]; routine serologic testing for this purpose should be discouraged.

Veterinarians and their lay staff caring for cats probably are at increased risk, and special precautionary measures must be exercised to protect pregnant personnel. Large numbers of cats are handled annually by animal practitioners and staff members, and as many as 1% of these cats may excrete oocysts. Feces from caged cats should be collected (preferably on a disposable tray or material) and discarded daily (preferably incinerated) before sporulation occurs. Care must be taken in handling feces for worm counts and similar procedures; samples should be examined within 24 hours of collection, and caution must be exercised to avoid contamination of hands, centrifuges, benches, and microscopes. Gloves should be worn at all times by those handling cat feces [896,899]. Pregnant veterinarians and their lay staff who are not seronegative may wish to consider having someone else handle materials potentially contaminated by oocysts.

### Serologic Screening, Diagnosis, and Treatment in Pregnancy

Only a serologic screening program during gestation will detect the acute acquired infection and thereby facilitate diagnosis and treatment of the infected fetus and newborn.

The cost-effectiveness of systematic screening of women during pregnancy depends on a variety of factors, including the cost of tests and how frequently they are employed compared with the cost to society of caring for the diseased children who would be born in the absence of screening [403,628,900–905]. Wilson and

Remington [628] and McCabe and Remington [890] proposed that a screening program be considered in the United States. Such a program would include the performance of a serologic test equal in sensitivity, specificity, and reproducibility to the Sabin-Feldman dye test in all pregnant women. It is crucial that initial testing be performed as early as possible, but at least by 10 to 12 weeks of gestation. (Ideally, testing of all women just before pregnancy would identify those at risk.)

Discussion of all of the pros and cons of a systematic screening program for the United States is beyond the scope of this chapter. Of importance in this regard, however, is the fact that approximately 50% of women with children in the NCCCTS from 1981 to 1998 could not identify a risk factor for or illness consistent with toxoplasmosis [893]. Certain recent analyses of this subject warrant consideration. These analyses have been discussed by Boyer and colleagues [893] as follows:

There are economic analyses, Cochrane database reviews, and metareviews that address the value of screening programs and their outcomes. Some of these analyses and reviews have considered both well-performed studies and studies of dissimilar cohorts that have been inadequately designed, controlled, performed, or interpreted to be of equal value. Some authors of these analyses have noted that there are no perfectly designed and performed prospective, randomized, placebo-controlled studies that have follow-up and include economic analyses that clearly document savings in costs and efficacy of newborn or maternal screening.

Some investigators who have reviewed the available data concluded that without better prospective studies, it may be too costly or unwarranted to perform universal screening and treatment, even to prevent suffering, health care-related costs, loss of productivity and limitation in quality of life associated with untreated congenital toxoplasmosis. There are comments that such screening could cause unacceptable anxiety as a result of false-positive test results, or unnecessary pregnancy terminations due to serologic testing that was not confirmed in a high-quality reference laboratory or counseling that was suboptimal. In contrast, others have concluded that screening, in conjunction with careful confirmation in a high-quality reference laboratory and knowledgeable and caring counseling, is important to facilitate identification and treatment of this fetal and newborn parasitic encephalitis and retinitis.

We critically reviewed these analyses and the concerns they raise. Some important considerations are presented next. We conclude that a number of studies on this subject are seriously flawed. Fortunately, a number of carefully designed investigations on this subject have been performed as well. These latter works indicate that systematic detection of this infection in pregnant women and treatment of the infected fetus as described by Daffos and associates [906] result in better outcomes [893]. In the cohort described by Wallon and colleagues [765], improved outcomes for affected children were observed. Careful confirmation of serologic testing in a high-quality, reliable reference laboratory, and knowledgeable and empathetic medical care and counseling, is essential [893]. Another study performed by Gras and coworkers in a cohort of mothers in Lyon, France, examined the effect of prenatal treatment on the risk of intracranial and ocular lesions in children with congenital toxoplasmosis [907]. This cohort included 181 infected children born to mothers who received treatment during gestation. The infants received 3 days of pyrimethamine and 3 weeks of sulfadiazine at approximately the time of birth, followed by 2 to 5 weeks of spiramycin therapy and then 12 or more months of Fansidar administered every 10 days. Thirty-eight children had hydrocephalus, intracranial calcifications on ultrasound study or skull film, or in one instance on CT scan, or ocular lesions detected by 3 years of age. These authors report the following percentages of retinal lesions detected over time: 4% (1 month), 9% (6 months), 11% (12 months, N = 157), 16% (3 years, N = 133), 19% (5 years, N = 96), 23% (7 years, N = 55). Because the locations of eye lesions that were apparently new were not clearly specified and not documented with photographs throughout the study, it is difficult to determine with certainty whether the lesions observed later were missed on initial examinations (which are more difficult in young infants and children) or truly were new lesions.

Gras and coworkers also state that, with one exception, outcomes were the same whether the mothers received no treatment, spiramycin, or pyrimethamine plus sulfadiazine before the infants were born. They [907] further reported an observation that is unusual and difficult to explain: They noted the best outcome (i.e., fewest intracranial lesions) with no treatment in utero or following the greatest delay in treatment in utero. The method of detection of intracranial lesions appears to have been by postnatal skull radiography or head ultrasound examination [907], both well known to be suboptimal in terms of sensitivity. The authors suggest that perhaps this result of improved outcome with less treatment could be due to immune suppression in the mother or fetus by pyrimethamine or sulfadiazine treatment, but they provide no supporting data for this hypothesis. The prenatal treatment modalities differed from those used in the cohorts reported by Hohlfeld and colleagues in Paris [77], and the treatment and methods of evaluation conducted postnatally differed from those described by the NCCCTS [433].

Hohlfeld and colleagues noted diminution of cerebrospinal fluid abnormalities indicative of active encephalitis when in utero treatment with pyrimethamine and sulfadiazine was used [76], and Couvreur and associates noted a reduction in isolation of *T. gondii* from placental tissue [69]. Without treatment, *T. gondii* can be isolated from approximately 90% of placentas. With treatment (initiated between 15 and 35 weeks of gestation; median, 23 weeks) *T. gondii* was isolated from placentas of approximately 77% of women given spiramycin [69] and approximately 42% of women given pyrimethamine plus sulfadiazine with leucovorin [69]. *T. gondii*-specific IgM antibody was present in fewer newborns born to mothers given pyrimethamine plus sulfadiazine than in the number of newborns born to mothers who received no treatment (17% versus 69%), and infection was more often subclinical in the newborns born to mothers who had treatment (33% versus 57%) [76].

Foulon's data [78] also are noteworthy: Effects of treatment on development of sequelae in the fetus and the infant up to 1 year were analyzed in 140 children. Sequelae were present in 7 (28%) of 25 children born to mothers who did not receive treatment and in 12 (10%) of 115

children born to mothers who did receive treatment. Multivariate analysis revealed that administration of antibiotic treatment was predictive of the absence of development of sequelae in children ($P = .026$; odds ratio 0.30; 95% confidence interval 0.104 to 0.86). Moreover, when antibiotics were used, a positive correlation was noted between development of sequelae and the time elapsed between when infection occurred and the start of treatment. More rapid instigation of antibiotic treatment after infection led to less frequent sequelae found in the newborn. ($P = .021$).

The NCCCTS investigators have noted resolution of a number of parameters including hepatitis, active chorioretinitis, meningoencephalitis, and no new eye lesions during sustained treatment for congenital toxoplasmosis during the first year of life [433].

Brezin and colleagues reported that 7 (39%) of 18 children with congenital toxoplasmosis treated in utero had eye lesions, with posterior pole lesions in four and with visual impairment in only one child [79]. The median duration of follow-up was 4.5 years (range 1 to 11 years). They were infected before 25 weeks of gestation. They had received in utero treatment before 35 weeks of gestation but not earlier than 22 weeks. Treatment was continued after birth until they were 1 year of age. Children in the NCCCTS also were infected early in gestation, but their mothers had not received treatment during gestation. In contrast with the French children who had received treatment in utero and had less severe eye disease, the children in the NCCCTS had a predominance of posterior pole eye lesions: 54% of children who received treatment in their first year of life, 82% of children with infection detected after their first year of life and therefore untreated, and 58% of the total.

Considerable discussion [908] is available on two recent studies of the efficacy of prenatal treatment in prevention and reduction of sequelae of the congenital infection. The commentary of Thulliez and coworkers is reproduced here in its entirety because of the importance of this analysis in understanding the strengths and weaknesses of the published data:

In their retrospective cohort study of 554 mother-child pairs, Gilbert and colleagues did not detect a significant effect from prenatal treatment on the risk of vertical transmission of toxoplasmosis [909]. This result is not surprising because there were very few untreated women and the analysis of no treatment versus pyrimethamine-sulphadiazine was restricted to half of the cohort who did not undergo amniocentesis. The confidence interval (0.37 to 3.03) for the odds ratio (1.06) for no treatment compared with pyrimethamine-sulphadiazine was therefore very wide and could include a doubling in the risk of transmission in untreated women. Thus an absence of evidence of prenatal treatment effect does not exclude a clinically important beneficial effect.

A further problem is that most of the untreated women were infected during the third trimester of pregnancy. Figure 31–4 shows that only three women infected before 28 weeks of gestation were not treated. The remaining 28 untreated women were infected after 28 weeks. The effect of treatment in the third trimester cannot be generalized to the whole of pregnancy. Finally, the authors explain their findings by suggesting that vertical transmission occurs soon after infection, during parasitemia. This hypothesis is not supported by any scientific studies in humans. On the contrary, one study found that the sensitivity of prenatal diagnosis was lower in early than midpregnancy, suggesting that vertical transmission may be delayed for some women infected in early pregnancy [206].

In the second report by Gras and colleagues [907], the authors unexpectedly found no evidence that prenatal treatment with pyrimethamine-sulphadiazine was more effective than spiramycin in reducing the risks of intracranial or ocular lesions in congenitally infected infants by 3 years of age. A potential explanation for this result is that mothers who transmitted the infection to their fetus soon after infection were more likely to be treated with pyrimethamine-sulphadiazine than mothers infected at the same gestation but in whom transmission was delayed until later in the pregnancy. These two groups may not be comparable because fetuses infected earlier in pregnancy have a higher risk of clinical signs. This explanation is suggested by the fact that mothers infected before 32 weeks were only given pyrimethamine-sulphadiazine if the diagnosis of fetal infection was positive (i.e., vertical transmission occurred between maternal infection and the date of fetal sampling). Other mothers infected before 32 weeks were treated with spiramycin until delivery, either because the prenatal diagnosis was negative or not attempted. In this latter group, transmission occurred either after amniocentesis or at some unknown time between the date of maternal infection and delivery; that is, later during gestation than in the group receiving pyrimethamine-sulphadiazine.

There are two further explanations for the lack of effect of pyrimethamine-sulphadiazine. First, there was a long delay before pyrimethamine-sulphadiazine was started. This was because the study was carried out more than 6 years ago, when mouse inoculation was the standard fetal diagnostic test [83] and pyrimethamine-sulphadiazine treatment would have been delayed for 3–6 weeks until results were known. Today, PCR analysis of amniotic fluid is widespread. Results are available in one day and women with infected fetuses are treated much earlier [522]. Secondly, women in the study given pyrimethamine-sulphadiazine actually received an alternating regimen with spiramycin. The periods of spiramycin treatment may have led to parasitic relapses in fetal tissues, as shown in experimental models (Piketty and colleagues, AAC, 1990). The current treatment policy for women with a positive prenatal diagnosis is to prescribe continuous treatment with pyrimethamine-sulphadiazine until delivery.

The data reported by Gilbert and colleagues [910] and Gras and coworkers [911] provide no convincing evidence that this policy should change.*

Each of us is in favor of a screening program for the United States similar to that being used at present in France (see Fig. 33–35). We recognize, however, that constraints of the present-day health care systems may not permit such screening on a monthly basis or, in some instances, screening of pregnant women per se. Cost-benefit analyses are especially relevant to mandated,

*Reproduced from Thulliez P, et al: Efficacy of prenatal treatment for toxoplasmosis: a possibility that cannot be ruled out. Int J Epidemiol 30:1315–1316, 2001. Reference numbers and cited figure refer to main text.

state-supported screening programs. Nevertheless, we believe that almost all parents, given the choice, would select a simple, not very costly, and direct measure that could prevent cognitive and ocular damage to their child as part of their health care coverage.

Introduction of prenatal screening and, in particular, use of PCR testing on amniotic fluid at 18 weeks of gestation has altered the approach to screening of women. The data that demonstrate a benefit of screening are from programs that screen on a monthly basis, as is done in France. In France, more than 90% of women now have their first prenatal visit (with testing to assess whether they are seropositive for *T. gondii* antibodies) in the first trimester. This early, first-trimester prenatal visit is a requirement for health care insurance coverage during gestation and at birth. This requirement considerably facilitates interpretation of results of serologic screening. Possible alternatives in locations where prevalence of antibody is low and resources are limited have not been studied systematically.

Available data indicate that better outcomes result with initiation of treatment within weeks after the diagnosis of recently acquired infection is made in the mother [78]. (This conclusion is also supported by the recent meta-analysis by the SYROCORT study group of 1438 mothers who were treated during pregnancy as part of 18 different European screening cohorts [912].) This analysis showed that the earlier prenatal treatment commenced following seroconversion the lower the risk of transmission with an odds ratio (adjusted for timing and type of prenatal treatment) of 0.48 in mothers treated less than 3 weeks after seroconversion, compared with odds ratio of 0.60 to 0.64 in mothers treated 3 to 8 weeks after seroconversion and to the reference value of 1.0 for mothers treated more than 8 weeks after seroconversion. This meta-analysis shows that early treatment following seroconversion is more effective than delayed treatment in preventing mother to infant transmission. Thus although no randomized controlled trials comparing treatment to no treatment have been performed, unless delayed treatment increases the risk of transmission compared to no treatment, a possibility we consider to be unlikely, then early treatment is beneficial. Accordingly, these findings support the notion that early testing would allow the detection of women whose fetuses are at greatest risk of being infected and appropriate management decisions to be made regarding treatment.

If the diagnosis of newly acquired maternal infection has been made, it becomes important to determine as early as possible whether the fetus has been infected because treatment of the fetus through administration of specific therapy to the pregnant woman may be indicated (see later discussion). PCR analysis of amniotic fluid allows fetal infection to be detected. Therefore, women must be informed of the importance of a visit to their physician as early as possible in pregnancy to allow for early serologic testing. Under optimal circumstances, if a pregnant woman is seronegative at the time of her first prenatal evaluation, serologic follow-up testing should be performed monthly thereafter to allow for timely recognition of newly acquired infection. This is the approach with the greatest potential for benefit. We recognize that such frequent testing may not be feasible. If it is not, blood for the second serum sample should be drawn at a time in the second trimester such that if recently acquired infection is confirmed, PCR analysis in the amniotic fluid can be performed at 18 to 21 weeks of gestation. If that second serum does not reveal recently acquired infection, a third serum sample can be obtained in the early third trimester. If seroconversion is observed at that time, we recommend PCR on amniotic fluid; if the PCR assay reveals infection in the fetus, the mother should receive pyrimethamine-sulfadiazine in an attempt to treat the fetus. A final serum sample is obtained at the time of parturition to detect those mothers who acquired their infection very late in gestation but whose fetuses are at greatest risk of infection. Luyasu and associates [913] reported seven cases of subclinical congenital *T. gondii* infection in infants born to mothers who acquired their infection between 2 and 4 weeks before delivery. They emphasized that because children born to mothers who become infected close to term are at greatest risk for development of the congenital infection and must be given appropriate treatment to attempt to prevent untoward sequelae of the infection, it is important to screen seronegative pregnant women until the time of delivery.

A woman whose is seropositive on initial testing ideally then undergoes testing for IgM antibodies. If the IgM test result is positive, an avidity test should be performed on the same serum sample. If a high-avidity test result is observed in a woman in her first trimester, acute infection during the first trimester is essentially excluded. For further decisions regarding patient management and desirability of confirmatory testing if the IgM test result is positive and the avidity test titer is low or equivocal, the reader is referred to the discussion in the “Avidity Assay” section and the section “Practical Guidelines for Diagnosis of Infection in the Pregnant Women.” In patients with a positive IgG test result and a negative result on testing for IgM antibodies in the first trimester, with no clinical signs of acute toxoplasmosis, no further testing would be performed because in the United States the probability that these women are acutely infected is remote.

In addition to the data described above that show the importance of early, monthly serologic screening, if the risk of maternofetal transmission is to be reduced by antenatal treatment, early detection and antenatal treatment may reduce the risk of subsequent sequelae in those who do become infected. The data of Brézin and associates indicate that subsequent retinal disease is less frequent, and also less severe, in the infants born to mothers managed according to the method used by the group in Paris [886]. Similarly, Foulon and colleagues showed that earlier initiation of antenatal treatment was associated with a decreased risk of sequelae by 1 year of age [78]. However, reports by Gras and colleagues [911] and the meta-analyses done by the SYROCOT [912] study group concluded that antenatal treatment did not reduce the risk of ocular sequelae even when started within 5 weeks of seroconversion, although there was a trend suggesting that early antenatal treatment may reduce the risk of intracranial lesions; neurologic follow-up is still in progress [195].

The basis for these conflicting conclusions regarding the impact of antenatal treatment on ocular sequelae is unclear. However, comparison of two recent reports that

reached contrasting conclusions [914,915] raises the possibility that studies like SYROCOT, which group together cases from multiple centers whose approaches to prenatal diagnosis and treatment vary substantially, may obscure significant findings observed at centers whose frequency of screening and approach to intervention are done according to the method used in Paris. Freeman and coworkers [914] analyzed 281 cases from multiple centers throughout Europe and concluded that prenatal treatment did not decrease the incidence of retinochoroiditis. Among these 281 cases were 129 from three centers in France whose approach to antenatal management paralleled the method used in Paris, whereas the remaining cases came from centers in multiple countries with quite different approaches. By contrast to the conclusions reached by Freeman and coworkers, when Kieffer and colleagues [915] analyzed the 129 cases from the three centers in France and an additional 171 cases from these centers, they found that when antenatal therapy was not administered within 8 weeks of seroconversion, the risk of retinochoroiditis was significantly greater (hazard ratio 2.54; 95% confidence interval 1.14 to 5.65) than when therapy was administered within 8 weeks of seroconversion. While there are other possible explanations for the discordant conclusions in these two and other studies, these findings are compatible with the interpretation that early detection of infection permits prompt treatment of infection that otherwise causes irreversible destruction of ocular and CNS tissue in utero.

We agree with Kieffer and coworkers [915] that while a randomized, controlled trial would be required to conclusively resolve these discordant conclusions, the evidence cited above suggests that monthly screening and early antenatal therapy may be warranted to reduce the risk of eye disease attributable to congenital toxoplasmosis. Although postnatal treatment can lead to rapid resolution of active infection and improve outcome [433] some children given treatment do not experience significant improvement; and even for those who function normally, the in utero infection is not without late consequences because cognitive outcomes for children who receive treatment are in some instances less favorable than for their uninfected siblings [873]. For these reasons, we currently consider that antenatal diagnosis and management is preferred when possible.

At present in the United States, *T. gondii* serology is performed haphazardly by laboratories and with kits of varying quality for physicians who may understand little of the disease or the tests, and unfortunately, in many cases inappropriate decisions are made on the basis of unreliable information [631,652]. For these reasons, our present lack of systematic screening—in a setting of sporadic screening that is inadequately supervised—may result in more harm than good. We and the FDA recommend that any serologic test results suggesting that infection was acquired during pregnancy be confirmed and interpreted by a reference laboratory before decisions regarding treatment, prenatal diagnosis, or therapeutic abortion are made [652,712].

We recently proposed guidelines [199] for serologic screening and management of women who are suspected or confirmed to have acquired toxoplasmosis during pregnancy in the United States. These guidelines are outlined in the form of management algorithms in Figures 31–38 and 31–39. Serologic testing for both IgG and IgM antibodies should be performed initially at clinical, nonreference laboratories. In most cases, testing in early gestation will confirm that the mother has not previously been infected, as indicated by the absence of IgG and IgM antibodies, and in other cases, that infection was acquired in the distant past, as indicted by the presence of IgG antibodies in the absence of IgM antibodies. Additional testing at a reference laboratory is required primarily in those women with IgG seroconversion or positive or equivocal IgM antibody test results. It is important to recognize that a positive IgM antibody test at any time during gestation does not necessarily indicate recently acquired infection. The greatest value of a positive IgM test is that it indicates the necessity for performing confirmatory testing in a reference laboratory before any conclusions regarding the presence or absence of recently acquired infection and risk to the fetus can be made.

### Special Usefulness of the Avidity Assay Earlier in Gestation

Recently, several tests for avidity of *Toxoplasma* IgG antibodies have been introduced to help discriminate between recently acquired and distant infection [88,283]. The commercial tests are available in Europe but are not licensed in the United States. Results are based on the measurement of functional affinity of specific IgG antibodies [88,283]. IgG affinity, which initially is low after primary antigenic challenge, increases during subsequent weeks and months by antigen-driven B cell selection. Protein-denaturing reagents, including urea, are used to dissociate the antibody-antigen complex. The avidity result is determined by using the ratios of antibody titration curves of urea-treated and untreated samples.

The use of the avidity test in the acutely infected woman during the first 12 to 16 weeks of gestation was recently described [88]. The usefulness of testing for IgG avidity was evaluated in a reference laboratory in the United States. European investigators have reported that high-avidity IgG *T. gondii* antibodies exclude acute infection in the preceding 3 months. In this U.S. study, 125 serum samples taken from 125 pregnant women in the first trimester were chosen retrospectively because either the IgM or differential agglutination (AC/HS) test in the *Toxoplasma* Serologic Profile suggested or was equivocal for a recently acquired infection. Of 93 (74.4%) serum samples with either positive or equivocal results in the IgM ELISA, 52 (55.9%) had high-avidity antibodies, which suggests that the infection probably was acquired before gestation. Of 87 (69.6%) serum samples with an acute or equivocal result in the AC/HS test, 35 (40.2%) had high-avidity antibodies. Forty women were given spiramycin in an attempt to prevent congenital transmission, and 7 (17.5%) had high-avidity antibodies. These findings highlight the value of IgG avidity testing of a single serum sample obtained in the first trimester of pregnancy for IgG avidity.

The avidity test does not establish the diagnosis of the acute infection. At present, definitive serologic diagnosis of acute infection during gestation can be made only if paired serum samples reveal a significant increase in titer, most often of IgG antibodies [88,283]. Such increasing

titers are not commonly seen in pregnant women in the United States because no systematic serologic screening to detect seroconversion is done. Although successful screening programs have been used in France and Austria for many years, in the United States, usually only a single serum sample is submitted for testing, frequently late in gestation (see Table 31–23). It is noteworthy that more than 57% of these sera were obtained from pregnant patients after the first trimester of gestation, and 14% to 21%, after the second trimester of gestation. Use of such relatively late-gestation serum samples clearly demonstrates the difficulty in attempts to prevent transmission to the fetus in the United States. Results have not changed in the past several years. As noted, almost all women in France (95%) seek prenatal care in the first trimester because government medical benefits are then made available for the remainder of the pregnancy. Early prenatal care permits initiation of serologic screening early in gestation. This approach contrasts remarkably with that used in the United States.

Because IgM antibodies may persist for months or even years after acute infection, their greatest value is in determining that a pregnant woman was not infected recently. A negative result virtually rules out recent infection, unless serum samples are tested so late after onset of infection that IgM antibody has disappeared or so early in acute infection that an antibody response has not occurred or is not yet detectable. When results are positive, a number of additional serologic tests, including those for the detection of IgG, IgA, and IgE antibodies, and a combination of these tests, the *Toxoplasma* Serologic Profile (TSP), can help discriminate between recently acquired and distant infection. The differential agglutination (AC/HS) test most closely approaches a single reference standard test for the discrimination of recently acquired and distant infection. At present in the United States, however, this test is done only by the *Toxoplasma* Serology Laboratory at the Palo Alto Medical Foundation (TSL-PAMF) in Palo Alto because the required antigen preparations are not commercially available. In addition, as is true for IgM antibodies, an acute pattern in the AC/HS test may persist for longer than 1 year.

Liesenfeld and coworkers investigated the usefulness of testing for avidity of IgG antibodies in a *Toxoplasma* serology reference laboratory in the United States that processes serum samples primarily from pregnant women [88]. In most cases, the physician requests information about the time of onset of the infection on the basis of results obtained from a single serum sample. The goal of these investigators was to compare results obtained in an IgG avidity test with those obtained in the IgM ELISA and AC/HS tests.

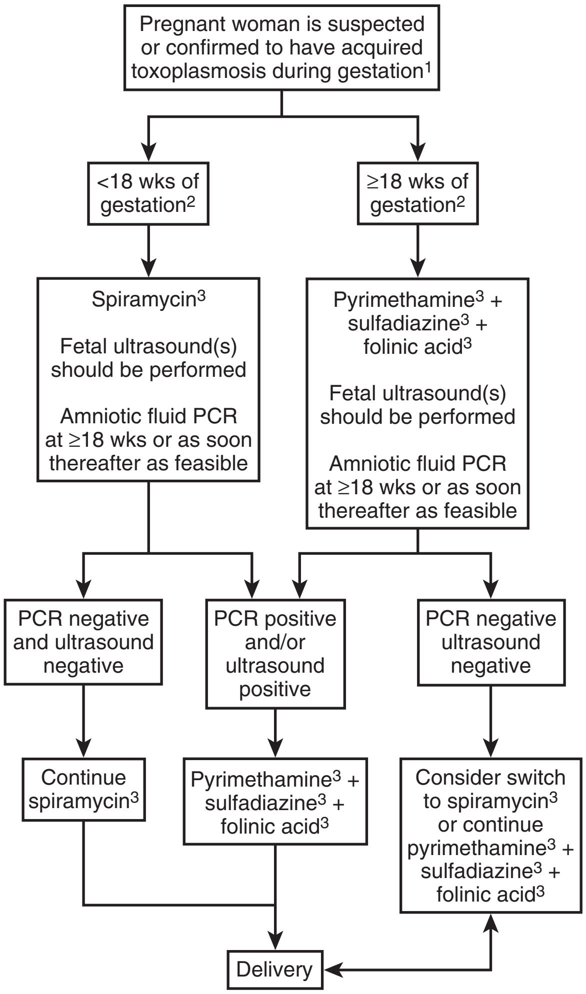

**FIGURE 31–39** Approach for pregnant women who are suspected or confirmed to have toxoplasmosis acquired during gestation. **1**, Consultation with a reference laboratory or physician expert in toxoplasmosis is suggested (i.e., Palo Alto Medical Foundation Toxoplasma Serology Laboratory, telephone number (650) 853–4828, or US [Chicago, IL] National Collaborative Treatment Trial Study, telephone number (773) 834–4152). **2**, Gestational age at which maternal infection was suspected or confirmed to have been acquired (or the best estimate); this is not the gestational age at which the patient consulted with or was seen by the health care provider. **3**, For dosages and comments, see Table 31–6. Clin Infect Dis 47:554–566, 2008.)*

All pregnant women who have a positive result on IgM *T. gondii* serologic testing should have an IgG avidity test performed. This test is most valuable in the first 12 to 16 weeks of gestation (see under "Diagnosis"). In two reference laboratories, the results from the AC/HS test complement the information provided by the avidity assay. The avidity assay is particularly useful in the first 4 months of gestation when IgM is present and the AC/HS test result is acute or equivocal. Time of conversion from low or equivocal to high avidity is highly variable among persons tested. Once a high-avidity test result is obtained, it can be concluded that the patient was infected at least 3 to 5 months earlier. Low-avidity test results should not be interpreted to mean recently acquired infection. The reason is that low-avidity antibodies may persist for as long as 1 year, and borderline or low-avidity antibodies can persist in the presence or absence of *T. gondii*-specific IgM antibodies. Forty percent of women with *T. gondii*-specific IgG but no IgM antibodies had borderline or low-avidity antibodies in one study [89].

The avidity test is best used in conjunction with a panel of tests, for example, *T. gondii*-specific IgG, IgM, IgA, and AC/HS tests. The avidity test should not be used alone; results should be interpreted in the context of other serologic tests that indicate acute infection in the first 12 to 16 weeks of gestation. The avidity test can be used to assess whether acute acquired infection in the mother that is first detected late in gestation was acquired more than 12 to 16 weeks earlier. This provides information about risk to the fetus.

## Prevention of Congenital Toxoplasmosis Through Treatment of the Pregnant Woman

For the special instance of the pregnant woman with HIV infection, see earlier section on "Congenital *Toxoplasma gondii* Infection and Acquired Immunodeficiency Syndrome," under "Clinical Manifestations."

### *Acute Infection*

#### Antimicrobial Therapy

Treatment during pregnancy (see also "Treatment of the Fetus through Treatment of the Pregnant Woman") has been employed in an attempt to decrease both the incidence and the severity of congenital infection. This treatment is administered to a pregnant woman with a recently acquired (acute) infection in the hope that such treatment will prevent spread of infection to the fetus. The rationale for such treatment is based on the observation that there is a significant lag period between the onset of maternal infection and infection of the fetus. In the first such study, performed in Germany, Kräubig used a combination of sulfonamides and pyrimethamine [73,916]. Because of its potential teratogenic effects, pyrimethamine was not administered during the first 12 to 14 weeks of gestation. Kräubig noted a definite reduction in incidence of congenitally acquired infection in infants born to mothers who received treatment (5%) versus those who did not (16.6%)—a 70% reduction (prevention). Kräubig considered these data an indication that treatment is necessary if a diagnosis of acute acquired toxoplasmosis is made during pregnancy. Thalhammer, who closely collaborated in these studies with Kräubig, agreed with this statement because it appears that all cases of congenital toxoplasmosis might be prevented by such an approach [917,918]. In 1982, Hengst from Berlin reported similar results in a prospective study [919].

In a separate and independent study performed in France [68], daily oral doses of 2 to 3 g of spiramycin in four divided doses were administered for 3 weeks to women who acquired toxoplasmosis during pregnancy. Such courses of treatment were arbitrarily repeated at 2-week intervals up to the time of delivery. Only women who completed at least one such course were considered to have undergone treatment. Cases of congenital *T. gondii* infection were significantly more frequent among

154 women who received no treatment (58%) than among 388 women who received treatment (23%). Clinically apparent disease in the newborns, however, was just as frequent among children born with congenital *T. gondii* infection from both groups of women (28% and 27% of infected offspring, respectively). This finding suggests that spiramycin treatment in the pregnant woman might have reduced by 60% the frequency of transmission of *T. gondii* to the offspring but did not apparently modify the pattern of infection in the infected fetus. Although the difference between treated and untreated groups is highly significant, however, the pregnant women in this study who received no treatment do not represent a good control group for several reasons. Most women diagnosed in their first trimester received treatment, whereas the proportion of women who received no treatment is rather low among women who acquired *T. gondii* infection during the last months of pregnancy. Thus more infections occurred earlier in the treated group than in the untreated group, a fact that of itself might have led to fewer congenital infections and to a higher proportion of cases with clinical disease among infected infants, if untreated. Nevertheless, congenital infections were less frequent in the treated group in each trimester of pregnancy. Consequently, the decrease in fetal infections could be assumed to reflect bias not only in the selection of cases but in treatment as well.

Variability in the clinical aspects of congenital infection also must be considered. Table 31–51 shows the comparison between treated and untreated groups of pregnant women. No difference in the proportion of mild and subclinical cases was found. By contrast, the number of stillbirths decreased and the proportion of children born alive with severe disease increased slightly in the treated group. The numbers are too small to be significant, but the reason for the increase in incidence of severe disease despite treatment during fetal life is that the treatment, although undertaken too late to prevent severe damage, might sometimes have prevented fetal death.

A prospective study that compares the efficacy of spiramycin versus pyrimethamine plus sulfonamide for prevention of congenital transmission has not been performed. When compared with data obtained from historical controls, the more recent studies suggest the importance of the pyrimethamine plus sulfonamide regimen. Each of the studies involved an attempt to isolate the organism from placentas. In one such study of 32 women, each of whose fetuses was diagnosed as being infected by isolation of the parasite from amniotic fluid or blood between weeks 24 and 30 of gestation (update of originally published data [69]), infection in the mothers was documented to have occurred between weeks 10 and 29 of gestation. The mothers were given 3 g of spiramycin daily as soon as the diagnosis of their acute acquired infection was made. Pyrimethamine plus sulfonamide was given during the last 2 months of gestation. Because of the potential hazard for mother or fetus, use of the combination of pyrimethamine plus sulfonamide was restricted by Couvreur and colleagues to the last 2 months of gestation and to a high-risk group in which fetal infection was documented during pregnancy. *T. gondii* was isolated from 47% of the placentas (examined after delivery) from these 32 cases. In marked contrast, *T. gondii* was isolated from 71.5% of placentas of 21 infants born to mothers who received spiramycin alone and, using historical controls, from 89% of placentas of 85 infants born to mothers who received an inadequate spiramycin regimen (duration of treatment less than 2 weeks or daily dose of only 2 g, which is considered by the investigators to be too low) or who received no treatment.

In Austria, Aspöck and colleagues routinely used spiramycin before week 16 of gestation and pyrimethamine plus a sulfonamide after week 15 of gestation. In their prospective study, this treatment regimen was highly successful [900].

Together, these data strongly suggest that treatment is effective, although a placebo controlled randomized trial demonstrating such effectiveness has not been performed.. In addition, because spiramycin also may delay transmission of the parasite to the fetus, it should have the added benefit of reducing the severity of the disease in the fetus and newborn because of the increased maturity of the maternal immune response and of the fetus at the time infection occurs. Critically designed studies are needed to clarify this question. Nevertheless, until such data become available—and in view of the prevention rate of congenital infection of 60% to 70% achieved in the two studies mentioned earlier—it would appear prudent to advise treatment in women who acquire the infection during pregnancy. The dose of spiramycin is 3 g per day. Toxicity has not proved to be a problem with spiramycin in such cases. This drug is at present available in the United States only by request to the FDA. Pyrimethamine plus sulfadiazine can be employed in the second and third trimesters of pregnancy with the precautionary measures mentioned earlier in the "Therapy" section (see also "Treatment of the Fetus In Utero"). Whether sequelae in infected children who received treatment in utero are as frequent or as serious as those in children who received no treatment is a question that can be answered only by long-term observation.

Repeated here are our recommendations made previously in "Treatment of the Fetus through Treatment of the Pregnant Woman."

When the diagnosis of infection in the fetus is established earlier than 17 weeks, we suggest that sulfadiazine be used alone until after the first trimester, at which time pyrimethamine should be added to the regimen. The

decision about when to begin pyrimethamine/sulfadiazine/leucovorin for the pregnant woman is based on an assessment of the risk of fetal infection, incidence of false-positive and false-negative results of amniocentesis with PCR, and risks of medicines. Although reliability of PCR results are laboratory dependent, results from the best reference laboratories, have a sensitivity for PCR of the *T. gondii* 300 copy 529 bp gene with amniotic fluid of 92%. Thus PCR results reasonably determine the therapeutic approach.

When the mother becomes infected between 22 and 31 weeks of gestation, the incidence of transmission exceeds 50% and manifestations of infection in the fetus are substantial, 92% for 22 to 26 weeks and for 27 to 31 weeks. With maternal acquisition of infection after 31 weeks of gestation, incidence of transmission exceeds 60% and, manifestations of infection are in general less severe. Sensitivity of PCR in amniotic fluid is 92%.

When infection is acquired between 21 and 29 weeks of gestation, management varies. After 24 weeks of gestation, we recommend that amniocentesis be performed and that pyrimethamine/leucovorin/sulfadiazine be used instead of spiramycin. Consultation with the reference laboratory is advised.

In France, standard of care (until late in gestation) is to wait 4 weeks from the estimated time that maternal infection is acquired until amniocentesis to allow sufficient time for transmission to occur. Amniocentesis is not performed before 17 to 18 weeks of gestation. In some instances, when maternal infection is acquired between 12 and 16 weeks of gestation or after the 21st week of gestation, pyrimethamine and sulfadiazine treatment is initiated regardless of the amniotic fluid PCR result. This is because of concerns about the confidence intervals and reliability of negative amniotic fluid PCR results. When this approach is used, a delay in amniocentesis when maternal infection is acquired between 12 and 16 weeks and after 21 weeks of gestation would not be logical.

### Termination of Pregnancy

Confirmatory serologic testing in a reference laboratory and communication of the results and their correct interpretation by an expert to the patient's physician decreased the rate of unnecessary pregnancy terminations by approximately 50% among women with positive IgM *Toxoplasma* antibody test results reported by outside laboratories [88].

The decision whether to treat with antimicrobial agents or to perform an abortion in a woman suspected of acquiring *T. gondii* infection during pregnancy should ultimately be made by the patient in conjunction with her physician after careful consideration of the potential results with each of these two modalities of intervention. Therapeutic abortion may be considered in women who are known to have acquired acute *T. gondii* infection early during gestation or in whom the likelihood of their having acquired acute infection early during gestation is very high. Only approximately 22% of women who acquire primary *T. gondii* infection during the first 22 to 24 weeks of gestation transmit the infection to their offspring. Even if all women who acquire the infection during the first two trimesters were to elect abortion, less than one half of all cases of congenital toxoplasmosis would be prevented because more than 50% of infected offspring result from maternal infection acquired in the last trimester.

Prenatal examination has for the first time allowed for an objective decision by the pregnant woman in regard to abortion and whether her aborted fetus would indeed be congenitally infected. Such a decision was previously based on a statistical estimation of the risk to the fetus. Considerable controversy has arisen in regard to whether and under what circumstances abortion might be considered. The controversy appears to have stemmed from the publication by Berrebi and colleagues in *The Lancet* [736], who concluded that only ultrasonographic evidence of hydrocephalus indicates a poor outcome; for this reason they no longer use the gestational age-related statistics that Daffos and colleagues propose [82] to counsel affected couples. Berrebi's group [742] studied 163 mothers who acquired their infection with *T. gondii* before 28 weeks of gestation. All were given spiramycin treatment, and 23 also received pyrimethamine and sulfadiazine. Each underwent cordocentesis and regular ultrasound examinations. Their 162 live-born infants were evaluated over 15 to 71 months. Three fetuses died in utero, and 27 of 162 live-born infants had congenital toxoplasmosis: 10 had clinical signs of the infection, 5 with isolated or multiple intracranial calcifications, 7 with peripheral chorioretinitis, and two with moderate ventricular dilation. Because each of the 27 was free of symptoms and demonstrated normal neurologic development at 15 to 71 months of age, the investigators concluded that acute fetal infection identified in first- and second-trimester pregnancies need not be an indication for interruption of the pregnancy if fetal ultrasonographic evaluation results are normal (no evidence of fetal death or hydrocephalus) and treatment of the fetus is instigated.

In a letter to the editor of *The Lancet* commenting on the results of Berrebi and associates, Wallon and coworkers [869] also were conservative in their conclusions. From the results of their studies, they recommend that termination not be performed unless fetal ultrasonographic examination reveals morphologic abnormalities. In a simultaneously published letter to the editor of *The Lancet*, Daffos and colleagues [906] concurred that too many pregnancies are terminated because congenital toxoplasmosis is diagnosed prenatally, but these authors were far less optimistic than Berrebi and associates about the outcome for the fetus infected early in gestation. Daffos and colleagues stated that in a study of 148 fetal infections diagnosed by prenatal examination, "the best (and perhaps the only) factor with predictive value for the severity of the fetal infection is gestational age at the time of maternal infection." In their study, they noted that if the infection occurred before 16 weeks of gestation, 31 of 52 fetuses (60%) had ultrasonographic evidence of infection, including ascites, pericarditis, or necrotic foci in the brain, and 48% had cerebral ventricular dilation. If infection had occurred between 17 and 23 weeks, 16 of 63 fetuses (25%) had ultrasonographic signs, and only 12% had ventricular dilation. In those cases of infection after 24 weeks, only 1 of 33 fetuses (3%) had ultrasonographic signs, and none had hydrocephalus. Thus the approach that Daffos and his colleagues had recommended 6 years earlier [82] appeared to remain valid. These workers accept parental requests for

termination in those cases in which infection occurs before 16 weeks because of the severe prognosis for the fetus. In such instances, they have always found large areas of brain necrosis at necropsy, even when there was no evidence of ventricular dilation on ultrasound evaluation. They conclude that such dilation of the ventricles would have developed in many of these cases if the pregnancy had been allowed to continue, even if treatment with pyrimethamine and sulfadiazine was used.

Recently, Kieffer and coworkers [915] reported findings similar to the work of Berrebi and colleagues, that not all fetuses infected early in gestation had severe abnormalities when they were born. Like Berrebi and coworkers, they no longer concluded that early gestation infection of the pregnant woman uniformly had poor outcomes.

It is hoped that in the near future this issue will be resolved by a collaborative effort to review all pertinent data by interested investigators and, if necessary, to design studies aimed at formulating a consensus and guidelines for providing the patient with objective information during counseling about termination of pregnancy. In one study [206] in which real-time PCR analysis was evaluated, quantitation of the PCR revealed that higher parasite burden in amniotic fluid is associated with more damage to the fetus (see also section on "PCR").

Despite the fact that IgM tests do not differentiate between acute and chronic infection, a positive IgM test result strongly influences pregnant women in their choice to terminate or continue the pregnancy. In the United States, such decisions often are made on the basis of results for a single serum specimen in which the result of IgM antibody testing is positive and confirmatory testing is not done. We previously estimated that approximately 20% of women who are told that they have a positive result on IgM antibody testing will request therapeutic abortion [920]. In that study, approximately 60% of the results of IgM tests reported as positive by commercial laboratories were negative in the IgM test in the Palo Alto reference laboratory. In the cases with reported positive IgM test results, evidence of recently acquired infection, as determined by the *Toxoplasma* Serologic Profile, also was absent. Thus at a minimum, 12 of every 20 fetuses that were not infected were aborted. In a more recent study, Liesenfeld and associates [920] from the same laboratory determined the accuracy of *T. gondii* serologic test results obtained in commercial laboratories and the role of confirmatory testing in preventing unnecessary abortion. Congenital toxoplasmosis is a preventable disease. It is therefore the responsibility of health professionals who provide care for pregnant women to educate them on how they can prevent themselves from becoming infected (and thereby not place their fetus at risk). Lack of adoption of a systematic serologic screening program in the United States leaves education as the principal means of preventing this tragic disease.

Physicians who recommend or perform an abortion must be knowledgeable about the subject so that an intelligent decision can be made. Because abortions are performed as late as 22 to 24 weeks of gestation in the United States, the practitioner has time to obtain an initial serologic specimen early in gestation and a follow-up specimen later in gestation to define those women at risk of transmitting *T. gondii* to their offspring (see "Serologic Screening" section). Guidelines for the interpretation of serologic tests on specimens obtained during pregnancy have been given previously in the "Diagnosis" section. If tests for IgM antibodies to *T. gondii* are unavailable to assist in establishing the diagnosis of acute infection, it should be understood that the risk of congenital toxoplasmosis is almost zero in a patient whose serum shows a high IgG test titer in the second month of pregnancy. A high IgG test titer at that time indicates an infection that occurred at least 2 months before (and perhaps much earlier) in all but rare exceptions in which the serologic test titer rises steeply for several weeks. On the contrary, women who will later give birth to a congenitally infected infant, when examined during the second or third month of pregnancy, either have no antibody (i.e., they are not yet infected) or may have a low titer (associated with IgM antibody) as a result of an infection acquired during the past few days or weeks. A careful follow-up examination and confirmatory testing in a reference laboratory along with amniocentesis for PCR assay and mouse inoculation may reveal infection in the fetus in time to allow for consideration of termination of the pregnancy in these cases. Treatment for the infected mother to attempt to prevent transmission of the infection to the fetus appears more worthy of consideration in such circumstances.

### Chronic (Latent) Infection

The controversial subjects of congenital transmission, repeated abortion, and perinatal fetal mortality during chronic (latent) infection have already been discussed. A review of the pertinent literature on this controversy is available [921]. In an attempt to prevent infection and reduce fetal wastage, a series of women who had had previous abortions, premature births, or similar misfortunes were given pyrimethamine treatment by Cech and Jirovec of Prague [452]. A marked reduction in perinatal fetal mortality rate was observed in those women who received treatment. The investigators interpreted their results as showing a remarkable effect of pyrimethamine on the outcome of pregnancy in the skin test-positive women. Their results appear to be very favorable, but because the study was uncontrolled, these results must be interpreted with caution. Studies along the same line are those of Eckerling and associates in Israel [922] and others [923–925]. Results reported by Sharf and coworkers in Israel [926] suggested an etiologic relationship between latent maternal toxoplasmosis and spontaneous abortions, premature deliveries, and stillbirths. A number of such women were given pyrimethamine and triple sulfonamides before their next pregnancy and sulfonamides alone during pregnancy. The researchers interpreted their results as evidence that such treatment significantly increased the chance of a successful outcome of the pregnancy. Unfortunately, their controls were poorly defined and appear inadequate for statistical analysis.

Kimball and colleagues stated that, despite the association of antibodies to *T. gondii* with sporadic abortion noted by them, there is no evidence that therapy to prevent abortion should be administered routinely to

pregnant women with antibodies to *T. gondii*—even those with high titers [927]. In their series, there was a significantly greater incidence of abortions in patients with CF test titers of 1:8 or higher than in those with titers 1:4 or lower ($P < .01$). But they considered it unwarranted to recommend therapy to a group of pregnant women of whom only 10% could be expected to abort without therapy. Whether therapy for toxoplasmosis in patients with CF test titers of 1:8 or higher who are threatening to abort would be beneficial is unknown.

The question must now be raised whether there is sufficient evidence to warrant the routine prophylactic use of a drug with toxic and teratogenic potential against *T. gondii* in pregnant women who have positive serologic titers and a history of chronic abortion. Until the controversy is resolved by further evidence justifying the risk of therapy, the only conclusion that can be made is that pyrimethamine must not be used in such cases [928,929]. There are continued reports of use of such treatment [930].

## RESOURCES

A summary of useful resources with means to contact the relevant agencies is presented in Table 31–52.

## ACKNOWLEDGMENTS

We are sincerely grateful to Drs. Jacques Couvreur, Fernand Daffos, J. P. Dubey, Jose G. Montoya, Oliver Liesenfeld, and Kenneth Boyer for their advice and help in the preparation of this chapter.

We thank Drs. F. Daffos, and A.G. Noble for providing their data for inclusion in this chapter. We appreciate the assistance of Lara Kallal, Diana Chamot, Mari Sautter, and Peggy Wakeman.

The work on which this chapter is based was supported by grants AI 04717, AI 302230, AI 27530, and AI 16945 from the National Institutes of Health and the Research to Prevent Blindness Foundation.

CHAPTER

32

# Less Common Protozoan and Helminth Infections

Yvonne A. Maldonado

CHAPTER OUTLINE

Parasitic infections are highly prevalent in many developing areas of the world and may be common among pregnant women in developed countries. The placenta serves as an effective barrier, even in infections such as malaria and schistosomiasis in which systemic involvement and hematogenous spread are common. Although transplacental infections of the fetus are uncommon, the prevalence of parasitic infections among infants younger than 1 month is high in developing countries, and infections occur primarily through transmission during or shortly after birth.

In a study conducted in Guatemala, Kotcher and colleagues [1] found that 30% of newborns had acquired a protozoal infection by 2 weeks of age. Although these infants were infected with *Entamoeba histolytica* and *Entamoeba coli*, *Endolimax nana*, and *Iodamoeba buetschlii*, they remained asymptomatic. *Giardia lamblia* was found by the fifth week of life and *Trichuris trichiura* by the 16th week of life. A study conducted in a regional hospital in Togo revealed that 55% of infants and children from birth to 16 years old demonstrated evidence of parasitic infections in stool or urine, with obvious neonatal infections occurring as well [2].

*Pneumocystis jiroveci* (previously classified as *Pneumocystis carinii*) is considered in Chapter 34 [3].

## ASCARIS

*Ascaris lumbricoides* is the most prevalent parasitic infection worldwide, affecting up to 1 billion people. In humans, *Ascaris* eggs are ingested through fecal-oral contamination, hatch in the small intestine, and then penetrate the intestinal lumen to migrate extensively through blood and lymphatics. Larvae eventually reach the pulmonary circulation, where they migrate into the alveolar sacs, through the respiratory tree to the esophagus, and into the small intestine. Because *Ascaris* may migrate to many organs, worms are occasionally found in the uterus and the fallopian tubes [4].

Human fetuses apparently can mount an immune response to maternal *Ascaris* infection, and congenital infections are rare. Sangeevi and associates [5] studied the IgG and IgM responses to *Ascaris* antigens from matched maternal and cord bloods in south India and found evidence of fetal IgM directed against *Ascaris* antigens in 12 of 28 samples. Clinical status of the infants was not reported. Chu and coworkers [6], however, described an infant whose delivery was complicated by the simultaneous delivery of 12 adult *A. lumbricoides* worms. During preparations for a cesarean section, which was being undertaken because of prolonged premature labor and fetal distress, one worm passed from the vagina, and another was found in the vagina. When the placenta was removed, 10 worms were found on the maternal side of the placenta. The infant was delivered in good condition. The infant passed two female worms, which were 28 and 30 cm long, on the second and sixth days of life. He was treated with piperazine citrate, but no other worms were passed, and no eggs were seen after the 11th day of life. Fertilized ova of *A. lumbricoides* were found in the amniotic fluid and in the newborn's feces. An adhesion connected the mother's intestine and uterus, but it is uncertain whether the worms passed directly from the mother's intestine to the placenta and amniotic fluid, and were swallowed by the fetus; whether larvae passed hematogenously from the mother's lung to the placenta and thereby reached the fetal circulation, lung, and gastrointestinal tract; or whether female worms in the placenta produced fertile eggs that reached the amniotic fluid and were swallowed by the fetus.

DOI: 10.1016/B978-1-4160-6400-8.00032-8

Other investigators have reported fetal evidence of Ascaris infection in infants as young as 1 to 2 weeks old and in one infant with failure to thrive and bloody diarrhea at 3 weeks who responded to levamisole therapy [7].

# GIARDIASIS

*G. lamblia* causes a localized intestinal infection, with no systemic involvement, and *G. lamblia* infection in pregnancy has not been associated with fetal infection. Severe maternal infection that compromises nutrition can affect fetal growth, but such a severe illness is rare [8]. Neonatal *G. lamblia* infection can result from fecal contamination at birth. Infected infants are usually asymptomatic [9]. Treatment of pregnant women with giardiasis is generally deferred until after the first trimester unless symptoms are severe. There is some evidence that maternal antibody may be protective against neonatal giardiasis [10].

# AMERICAN TRYPANOSOMIASIS: CHAGAS DISEASE

Millions of people in Central and South America are infected by *Trypanosoma cruzi* and related protozoa. Because of the chronicity of these infections, they have a significant impact on public health. One estimate suggests that approximately 40,000 women and 2000 newborns may be infected on an annual basis in North America, primarily in Mexico, although up to 3780 infected pregnant women and 189 congenitally infected infants could be born among Hispanic populations in the United States [11].

## THE ORGANISM

The form of the organism that circulates in human blood is the trypomastigote. Cell division does not occur in the bloodstream. In tissue, the flagellum and undulating membrane are lost, and the organism differentiates into a leishmanial form, the amastigote [12,13]. Amastigotes multiply by binary fission, and masses of amastigotes are grouped into pseudocysts. The amastigotes in pseudocysts may evolve into trypanomastigotes and, on rupture of the pseudocyst, can gain access to the bloodstream or to new cells. Two strains of *T. cruzi* that cause human infections have been identified by biochemical differences among nine enzymes produced by the parasite [14].

## EPIDEMIOLOGY AND TRANSMISSION

*T. cruzi* infects primates, marsupials, armadillos, bats, and many rodents, including guinea pigs, opossums, and raccoons; birds are not infected [15]. Infection of insects and mammals with *T. cruzi* is most common between the latitudes 398N (i.e., northern California and Maryland) and 438S (i.e., southern Argentina and Chile) and on the islands of Aruba and Trinidad [1]. The usual vectors are in the family Reduviidae, subfamily Triatominae. The main vector in Venezuela is *Rhodnius prolixus*; in Brazil, *Panstrongylus megistus*; and in Argentina, *Triatoma infestans* (cone-nosed bug) [15]. These species are well adapted to human dwellings. Triatominae are hematophagous insects. They acquire and transmit the infection by biting infected vertebrates, including humans. The life span of the insect is not shortened by infection with *T. cruzi*; infected insects live up to a year after the onset of infection. In North America, the sylvatic habitat of the vector and the low virulence of the strains of *Trypanosoma* are responsible for the relative rarity of the disease. Colloquial terms used for the usual vector include the kissing or assassin bug in the southwestern United States; pito, hito, or vinchuca in Spanish America; and barbeiro in Portuguese America [16].

The vector is most commonly found in huts of mud and sticks and in other housing containing cracks. In vectors infected with *T. cruzi*, metacyclic trypomastigotes congregate in the rectum. Bites become contaminated when defecation occurs. The infective form reaches the bloodstream through the site of the bite or by penetrating mucous membranes, conjunctivae, or abraded skin [12]. *Trypanosoma rangeli* is spread by a few species of the triatomid bug. These metacyclic trypanosomes develop, divide, and multiply in the salivary gland. They are injected directly into the site of the bite.

Infections can also be acquired by blood transfusion [17] and transplacentally. The isoenzyme patterns of *T. cruzi* recovered from congenitally infected infants and their mothers are identical, but transplacental transmission may not always follow maternal infection with enzymatically similar strains [18].

## PATHOLOGY

### Placenta

The placenta is a relatively effective barrier to the spread of infection to the fetus [13]. The organism reaches the placenta by the hematogenous route and traverses the placental villi to the trophoblasts. After differentiation into amastigotes, the organism remains within Hofbauer (phagocytic) cells of the placenta until it is liberated into the fetal circulation [19–21].

Maternal parasitemia is greatest in the acute phase of infection; however, the period of intense parasitemia is short. Of the reported cases of congenital Chagas disease, only four have originated during the acute phase of infection [13]. Most congenital infections occur in infants born to women with the chronic form of the disease.

Infected placentas are pale, yellow, and bulky. They have an appearance similar to the placentas of infants with erythroblastosis fetalis. Infection of the placenta is much more common than infection of the fetus.

## BIOPSY AND AUTOPSY STUDIES

Two histologic types of lesions are recognized: those that contain parasites and those that do not [13]. In tissue sections, the parasite assumes the morphology of *Leishmania* bodies, which are round and contain an ovoid nucleus and a rodlike blepharoplast. Inflammation usually does not occur unless a pseudocyst ruptures. Tissue reactions induced by an antibody are believed to be responsible for lesions in which the parasite cannot be demonstrated. After infection, an antibody that cross-reacts with the endocardium, the interstitium, and the blood vessels of the heart is formed and is referred to as an endocardial-vascular-interstitial antibody [22–24]. This antibody has

an affinity for the plasma membranes of the endocardium, endothelial cell, and striated muscle, and for *T. cruzi*. Endocardial-vascular-interstitial antibody is present in 95% of persons with Chagas heart disease and in 45% of asymptomatic patients with serologic evidence of having had Chagas disease [24].

Tissue replication of the organism causes damage to the ganglia of the autonomic nervous system and to muscle [15]. Injury to the Auerbach plexus results in megaesophagus, megacolon, and dilation of other parts of the gastrointestinal tract and gallbladder. Similarly, the conducting system of the heart and the myocardium may be infected. Sudden death from arrhythmias can occur.

## CLINICAL MANIFESTATIONS

In the mother, urticaria is often present at the site of the bite, regardless of whether the insect was infected [12]. The favored site for the bite is the face, presumably because this is the part of the body that is most often exposed during sleep. In acute infections, an inflammatory nodule, referred to as a chagoma, may develop at the site of the bite. If the bite is on the face, it is often associated with a unilateral, nonpurulent edema of the palpebral folds and an ipsilateral regional lymphadenopathy (i.e., Romaña sign). Between 2 and 3 weeks after the bite, parasitemia, fever, and a moderate local and general lymphadenopathy develop. The infection can extend and involve the myocardium, resulting in tachycardia, arrhythmia, hypotension, distant heart sounds, cardiomegaly, and congestive heart failure. The latter feature is more severe in pregnant and postpartum women than in nonpregnant women. Hepatosplenomegaly and encephalitis also occur. The mortality rate during the acute phase is 10% to 20%. Death is usually attributed to cardiac dysfunction. Many survivors have abnormal electrocardiograms.

In the chronic phase, the placenta and fetus may be infected despite the fact that the mother is asymptomatic [12]. Chronic Chagas disease often comes to medical attention because of the occurrence of an arrhythmia. These patients often do not have signs or symptoms of congestive heart failure [15]. Of 503 patients with myocardiopathy of chronic Chagas disease studied by Vasquez [25], 19.8% died during an observation period of 6 years—37.5% suddenly and 55.2% with congestive heart failure.

## ABORTIONS AND STILLBIRTHS

Of 300 abortions in Argentina, 3 (1%) were performed because of Chagas disease [26]. In Chile and Brazil, 10% of all abortions are attributed to Chagas disease [12]. When the fetus is aborted, massive infection of the placenta is usually found.

## CONGENITAL INFECTIONS

Bittencourt and coworkers [27] found *T. cruzi* antibodies in 226 of 2651 pregnant women; 28.3% of seropositive mothers had parasitemia. Nevertheless, the risk of transmission to the fetus is low, and live births of infants congenitally infected with *T. cruzi* are rare. It is postulated that upregulation of fetal or neonatal immunity might be important in preventing vertical infection [28]. Congenital infections occur in 1% to 4% of women with serologic evidence of having had Chagas disease [1,12,13,21,29,30]. Among infants with a birth weight of 2500 g or more, congenital infections are rare [19,31–34]. Among low-birth-weight infants, congenitally infected infants can be premature or small for gestational age, or both. Congenital infections were found in 10 (2.3%) of 425 infants by Saleme and associates in Argentina [26], in 10 (2%) of 500 infants weighing less than 2000 g by Bittencourt and coworkers in Brazil [27], and in 3 (1.6%) of 186 infants with birth weights of more than 2000 g and in 1 (0.5%) of 200 premature infants with birth weights of 2000 g or less by Howard in Chile [35].

Congenitally infected infants may develop symptoms at birth or during the first few weeks of life. Early-onset jaundice, anemia, and petechiae are common. These symptoms are similar to those associated with erythroblastosis fetalis [13]. As occurs in older patients, congenitally infected infants may have hepatosplenomegaly, cardiomegaly, and congestive heart failure and have involvement of the esophagus leading to dysphagia, regurgitation, and megaesophagus [24,36]. Some infants have myxedematous edema. Pneumonitis has been associated with infection of the amnionic epithelium [37]. Congenitally infected infants can be born with encephalitis or can develop it postnatally. It is generally associated with hypotonia, a poor suck, and seizures [12]. The cerebrospinal fluid shows mild pleocytosis, which consists primarily of lymphocytes. Cataracts and opacification of the media of the eye have also been observed [29]. Both twins may be congenitally infected, or one may escape infection [38].

Of 64 congenitally infected infants for whom follow-up results were known, Bittencourt [13] reported that 7.8% died the first day, 35.9% died when younger than 4 months, 9.3% died between the ages of 4 and 24 months, and 42.2% survived for more than 24 months. Of those who survived for 2 years or longer, 74% had no serious clinical symptoms despite continued parasitemia. However, subclinical abnormalities might have been found if electrocardiography or radiography had been performed.

As with other congenital infections, the immune system of the fetus is stimulated. IgM antibody to *T. cruzi* and endocardial-vascular-interstitial antibody are formed [13,24].

## DIAGNOSIS

The diagnosis should be suspected at the time of abortions and stillbirths, and in infants who develop symptoms compatible with congenital infection. An easy, but often omitted, means of making a diagnosis of congenital infection is to examine the placenta for the amastigote of *T. cruzi*. The gross appearance of the placenta is similar to that seen in erythroblastosis fetalis. It appears that examination of infected amniotic fluid by PCR is not useful in diagnosing congenital infection [39].

Motile trypomastigotes can also be demonstrated by examining blood under a coverslip [13]. The number of parasites is low initially but increases subsequently.

Thin and thick smears can be examined after being stained with Giemsa stain. Microhematocrit concentration and examination of the buffy coat enhance the detection of parasites in congenital Chagas disease [40]. If more than 10 parasites/mm$^3$ are found, the infant generally dies [26].

Xenodiagnosis is performed by allowing laboratory-bred uninfected insects to feed and ingest the patient's blood. The fecal contents of the insects are examined for trypomastigotes 30 to 60 days later. Blood may also be injected into mice. In mothers with acute Chagas disease, the parasites are found in blood smears beginning 3 weeks after onset of the infection, and they persist for several months. Parasites can be demonstrated for years by xenodiagnosis.

In the chronic stages of the disease, the diagnosis can be made histologically by sampling skeletal muscle. The histologic appearance of the parasite in tissue sections is similar to that of toxoplasmosis. However, the amastigotes in Chagas disease contain a blepharoplast that is lacking in toxoplasmosis.

Several tests for antibody are available. Complement-fixing antibody crosses the placenta from mother to infant. This test, referred to as the Machado-Guerreiro reaction, demonstrates antibodies that exhibit a cross-reaction with *Leishmania donovani* and with sera from patients with lepromatous leprosy. In uninfected infants, complement-fixing antibodies are no longer demonstrable after the 40th day of life; in infected infants, these antibodies persist [13].

Agglutinating antibodies may also be demonstrable. Uninfected infants with titers of agglutinating antibody of 1:512 or less at birth have negative titers by 2 months of age [29]. The titer of agglutinating antibody in uninfected infants with initial titers of 1:1024 or higher becomes negative by 6 months of age. IgM fluorescent antibodies can be demonstrated in some infants, but infected infants do not always have a positive test result [24,38]. Data suggest that fetal IgG to specific acute-phase antigens may be useful in the diagnosis of congenital Chagas disease, but maternal and neonatal serologic tests using the microhematocrit, direct parasitologic visualization, and indirect hemagglutination or enzyme-linked immunosorbent assay have proved to be reliable [41,42].

## PROGNOSIS FOR RECURRENCE

Congenital infections can recur during subsequent pregnancies [43]. The same mother, however, often has healthy children before and after the affected one [24].

## THERAPY

In the past, various drugs, including nitrofurans, 8-aminoquinolines, and metronidazole, were thought to have some effect on the blood-borne form of the parasite. They were ineffective in eliminating the tissue form, the amastigote. There is no therapy available for prevention of congenital infection, but early detection of neonatal infection and treatment with nifurtimox has resulted in cure rates of up to 90% [44]. Information regarding treatment can be obtained from the Parasitic Disease Drug Service, Centers for Disease Control and Prevention, Atlanta.

## PREVENTION

The main means of prevention is to improve housing so that the vector cannot reach the inhabitants, especially during sleep. In endemic areas, potential blood donors should be tested, and only those who lack serologic evidence of having had Chagas disease should be permitted to donate blood. The addition of gentian violet (1:4000 solution) to blood has been useful as a means of preventing transmission of the infection to the recipient of the blood [15].

# AFRICAN TRYPANOSOMIASIS: AFRICAN SLEEPING SICKNESS

Whereas few cases of congenital disease have been reported, infection with *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* in adults is severe and often fatal, and congenital infection is most likely underreported. Humans are infected by the bite of an infected male or female tsetse fly, which injects trypomastigotes into the host. Humans are the primary reservoir for *T. gambiense* and large, wild game the hosts for *T. rhodesiense*. Once injected, the organism disseminates throughout the bloodstream. Signs and symptoms of infection appear after 2 to 4 weeks, and a chronic infection develops 6 months to 1 to 2 years later. The chronic stage includes a progressive meningoencephalitis, which is often fatal if left untreated. Infection with *T. gambiense* is associated with lymphadenopathy and is slowly progressive, whereas infection with *T. rhodesiense* is rapidly progressive.

The parasite can be transmitted transplacentally, but few cases have been reported [45,46]. Transplacental infection can cause prematurity, abortion, and stillbirth. Transplacental infection has been proved in infants who were born in nonendemic areas to infected mothers or if the parasite was identified in the peripheral blood in the first 5 days of life. Central nervous system involvement is common in congenital infection and, in some infants, may be slowly progressive.

The diagnosis should be suspected in an infant with unexplained fever, anemia, hepatosplenomegaly, or progressive neurologic symptoms whose mother is from an endemic area. The parasite can be identified in thick smears from peripheral blood or in the cerebrospinal fluid. In infants, treatment with suramin or melarsoprol has been reported with good results; however, in a case report of congenital trypanosomiasis [45], severe neurologic symptoms persisted after delayed diagnosis and treatment when the child was 22 months old.

# ENTAMOEBA HISTOLYTICA

There is some evidence that amebiasis during pregnancy may be more severe and have a higher fatality rate than that expected in nonpregnant women of the same age [47,48]. Abioye [48] found that 68% of fatal cases of amebiasis in females 15 to 34 years old occurred in pregnant women, whereas only 17.1% and 12.5% of fatal cases of typhoid or other causes of enterocolitis, respectively, in women in this age group occurred during pregnancy. Czeizel and coworkers [49] found a significantly higher

incidence of positive stool cultures for *E. histolytica* among women who had spontaneous abortions than among those who gave birth to living infants at term.

Amebiasis has been reported in infants as young as 3 to 6 weeks old [50–52]. In most instances, person-to-person transmission was considered likely, and the mother was the probable source of the infant's infection [50]. In one fatal case, the father had cysts of *E. histolytica* in his stool, whereas no evidence of infection with *E. histolytica* was found in the mother [51]. Perinatal infections have occurred in countries such as the United States in which the disease is rare.

Most infants reported with amebiasis in the perinatal period had illnesses with sudden, dramatic onset and were seriously ill. Bloody diarrhea was followed by development of hepatomegaly and hepatic abscess, rectal abscess, and gangrene of the appendix and colon with perforation and peritonitis. Persistent bloody diarrhea that is complicated by the development of a mass in or around the liver should lead to a thorough investigation about whether infection with *E. histolytica* could be the cause. Maternal amebiasis has also been associated with low birth weight [53].

Routine stool examinations for ova and parasites may be negative. Despite this, trophozoites of *E. histolytica* can usually be found in biopsy specimens of gastrointestinal ulcers and of the wall of the liver abscesses. The organisms cannot always be demonstrated in pus aspirated from the center of the abscess. An elevated indirect hemagglutination titer to *E. histolytica* can be helpful in diagnosing extraintestinal amebiasis. However, high titers are not usually seen until 2 weeks or more after onset of the infection in older patients and are not always present in neonates with severe extraintestinal infections [50]. Infants have been successfully treated with oral metronidazole [52]. Critically ill children should receive intravenous therapy with dehydroemetine or metronidazole.

# MALARIA

It is estimated that about half a billion malaria infections resulting in 1 million deaths a year occur worldwide [54]. Although malaria is recognized as the major health problem of many countries, its impact on pregnancy and infant mortality has probably been underestimated.

## THE ORGANISMS

Of the four species of malaria, *Plasmodium vivax* has the widest distribution, but *Plasmodium falciparum* tends to predominate in tropical areas. Malaria is spread to humans by the bite of anopheline mosquitoes. Of the many species of anopheline mosquito capable of becoming infected with malarial parasites, those that enter houses are more important than those preferring an outdoor habitat [55]. Mosquitoes that feed at night on human blood while the victim is asleep are the most important vectors.

After the bite of the mosquito, sporozoites are injected into the bloodstream but are cleared within one-half hour. The parasites mature in the parenchymal cells of the liver and form a mature schizont, which contains 7500 to 40,000 merozoites, depending on the species. The release of the merozoites results in the appearance of the ring stage in erythrocytes in the peripheral blood. Within hours, the parasite assumes an ameboid form and is referred to as a trophozoite. The sexual form is called a gametocyte. In infections with *P. vivax*, *Plasmodium malariae*, and *Plasmodium ovale*, all forms are seen in the peripheral blood from early ring forms through mature schizonts and gametocytes. In infections with *P. falciparum*, usually only rings and gametocytes are found in the peripheral blood.

## EPIDEMIOLOGY AND TRANSMISSION

In addition to transmission by the bite of mosquitoes, malaria can be transmitted by transfusion of blood products. In infants, this has occurred after simple transfusion and after exchange transfusion [56–59]. The onset of symptoms in neonates infected by blood products has varied from 13 to 21 days.

Malaria parasites survive in blood for weeks. Relapses can occur from *P. vivax* for up to 2 years and rarely for up to 4 years. Relapses from *P. malariae* have occasionally occurred 5 years or more after infection, but low-grade chronic parasitemia that is unassociated with symptoms is more common.

Malaria may be transmitted by reuse of syringes and needles and has spread by this route among heroin addicts. Infection in heroin addicts who become pregnant can result in congenital infections [60].

## PATHOLOGY

### Effect of Pregnancy on Malaria

The density and the prevalence of parasitemia are increased in pregnant women compared with women who are not pregnant but who reside in the same geographic area [61–65]. For *P. falciparum*, Campbell and colleagues [66] found a parasite density of 6896/mm$^3$ in pregnant women and 3808/mm$^3$ in nonpregnant women; for *P. vivax*, the parasite density was 3564/mm$^3$ for pregnant women and 1949/mm$^3$ for nonpregnant women. The prevalence and the density of the parasitemia decrease with increasing parity. Reinhardt and associates [62] found that the placenta was infected in 45% of primiparous women compared with 19% of women with a parity of five. This trend toward an increase in resistance to malaria with parity has been attributed by some to the increase in immunity that would be expected with an increase in age. However, the prevalence and the density of parasitemia are increased in pregnant women of all parities compared with those in nonpregnant women of the same parity [61–63]. This suggests that pregnancy, as well as age, is an important factor in determining susceptibility to malaria [61].

### Infection of the Placenta

The intervillous spaces of infected placentas are packed with lymphoid macrophages, which contain phagocytosed pigment in large granules. Lymphocytes and immature polymorphonuclear leukocytes are also present in large numbers. Numerous young and mature schizonts are

present. Trophozoites and gametocytes are uncommon [67,68]. Jelliffe [69] has suggested that the intensity of the infection in the placenta is related to the severity of the effect on the fetus. In general, the inflammatory response in placentas infected with *P. falciparum* is more intense than that in those infected with *P. malariae*.

## Effect of Malaria on Fetal Survival and Birth Weight

Up to 40% of the world's pregnant women are exposed to malaria infection during pregnancy. In those with little or no preexisting immunity, malaria may be associated with a high risk for maternal and perinatal mortality. Fetal and perinatal loss may be as high as 60% to 70% in nonimmune women with malaria [70]. In 1941, Torpin [71] reviewed 27 cases of malaria that had occurred in pregnant women during the preceding 20 years in a city in the United States. The maternal mortality rate was 4%, and the fetal mortality rate was 60%. In 1951, in Vietnam, Hung [72] found a fetal death rate of 14% among women who had infected placentas. Many of these women had had severe attacks of malaria during the first trimester and had sustained spontaneous abortions at that time.

Low birth weight is more common when the placenta is infected by parasites than when the mother is infected but the placenta is not [62,63,69,73,74]. The mean birth weight is lower if the placenta is infected with *P. falciparum* than if it is infected with *P. malariae*. Maternal anemia and placental insufficiency probably affect the fetus. It has been postulated that heavy infiltrations of parasites, lymphocytes, and macrophages interfere with the circulation of maternal blood through the placenta and result in diminished transport of oxygen and nutrients to the fetus [63]. The transport through the placenta of antibody to malaria may also be decreased when placental inflammation is severe [61].

Bruce-Chwatt [67] found that when the placenta was infected, infant weight at birth was an average of 145 g less than the weight of infants born to women with uninfected placentas. Similarly, Archibald [75] found infant weight at birth to be 170 g less, and Jelliffe [69,74] found it to be 263 g less in infants of women with infected placentas than in infants of women with uninfected placentas. In the studies performed by Bruce-Chwatt [67] and Jelliffe [69,74], 20% of the infants born to mothers with infected placentas weighed 2500 g or less, whereas 10% and 11%, respectively, of those born to mothers with uninfected placentas weighed 2500 g or less. Cannon [63] found that 37% of women who had infected placentas gave birth to infants weighing 2500 g or less, compared with 12% of those who had uninfected placentas. For primiparous women, 44% of those with infected placentas and 27% of those with uninfected placentas gave birth to infants weighing 2500 g or less [76]. Infants who have parasites demonstrable in their cord blood appear to be more severely affected than those who do not have parasitemia at the time of delivery; the mean weight gain of the mothers of these infants and the head and chest circumferences of the infants at birth are lower than expected [62]. Larkin [77] studied the prevalence of *P. falciparum* infection among 63 pregnant women and their newborns in southern Zambia and found peripheral parasitemia in 63% (40 of 63) of mothers and 29% (19 of 65) of newborns. Infected newborns had a mean average birth weight 469 g lower than uninfected newborns but did not have a higher incidence of preterm delivery.

Using the method developed by Dubowitz and associates [78] for scoring gestational age, Reinhardt and colleagues [62] found no evidence that the incidence of infants who were small for gestational age was increased when the placenta was infected. This finding suggested that low birth weight resulted from prematurity of infants born to women with malaria.

Jelliffe [69] observed that because malaria influences birth weight, it has an important effect on infant survival in countries in which it is endemic. In 1925, Blacklock and Gordon [79] found that 35% of infants born to mothers with infected placentas died within the first 7 days of life, whereas only 5% of those born to mothers with uninfected placentas died during this period. In 1958, Cannon [63] found that the mortality rate among infants 7 days old or younger was 6.9% for those whose mothers' placentas were infected, compared with 3.4% for those whose mothers' placentas were uninfected.

The data suggesting that malaria has an important influence on birth weight and therefore on infant survival have been given further credence by the demonstration by MacGregor and Avery [76] that control of malaria in a region is followed by an increase in mean birth weight of infants born there. After DDT spraying on the island of Malaita in the British Solomon Islands, the mean birth weight for infants of mothers of all parities increased by 165 g. For infants of primiparous women, the mean birth weight increased by 252 g [76]. There was a concomitant decrease in the number of infants with birth weights of 2500 g or less; the incidence of births in this weight range fell by 8% for all births and by 20% for infants of primiparous women [76].

Steketee and colleagues [80] reviewed studies between 1985 and 2000 and summarized the population attributable risk (PAR) of malaria on anemia, low birth weight, and infant mortality in malaria endemic areas. Approximately 3% to 15% of anemia, 8% to 14% of low birth weight, 8% to 36% of preterm low birth weight, 13% to 70% of intrauterine growth retardation and low birth weight, and 3% to 8% of infant mortality were attributable to malaria. Maternal anemia was associated with low birth weight, and fetal anemia was associated with increased infant mortality. It was estimated that 75,000 to 200,000 annual infant deaths are associated with malaria infection in pregnancy [80]. Malaria therefore contributes to fetal loss, stillbirth, prematurity, and neonatal death [74,81].

## Influence of Maternal Antibody on Risk of Infection

Antimalarial antibodies are transferred from the mother to the infant. The prevalence of precipitating antibody to *P. falciparum* within 24 hours of birth in Gambia was 87% in newborns and 87.5% in their mothers [82]. The prevalence of antibody in these newborns reflected the extent to which malaria had been controlled in the area

in which their mothers lived. In infants born in the provinces with more malaria, 97% had antibodies to malaria, whereas 75.8% of infants born in an urban area had antibodies to malaria.

Antibodies to malaria can be detected by complement fixation, indirect hemagglutination, and indirect fluorescence. Agglutinating and precipitating antibodies are also formed [83]. Levels of precipitating antibodies and antibodies detected by indirect hemagglutination decrease from birth to 25 weeks of age [84,85]. Subsequently, as a result of postnatal acquisition of infection, endogenous antibody synthesis begins and antibody levels rise.

Bray and Anderson [61] have suggested that the amount of IgG transferred to the fetus is decreased when the placenta is heavily infested with parasites. They found that women who were pregnant during the wet season in Gambia had higher mean antibody titers to *P. falciparum* than those who were pregnant during the dry season. This pattern reflected the mothers' serologic responses to the increase in exposure to malaria during the wet season. The antibody titers of the infants born to women who were pregnant during the wet season were not higher than those of infants born to women who had been pregnant during the dry season. The infants born to women who had been pregnant during the wet season had lower mean titers of antibody to malaria at birth than infants born during other seasons. In infants 2 to 3 months old, parasitemia was found in 32% born during the wet season but in only 3% to 15% born in other seasons.

## Other Factors Influencing Risk of Infection

Infants younger than 3 months have a lower than expected incidence of clinical disease, death from malaria, and parasitemia [82,84]. This has been attributed to a variety of factors, including the possibility that infants of this age are less exposed to and therefore less often bitten by mosquitoes. However, the two most important causes are probably the fact that the level of serologic immunity is high at this age and that fetal hemoglobin is present in the circulating red blood cells. Sehgal and associates [86] studied the role of humoral immunity in acquired malaria infection among newborns in Papua New Guinea. Among 104 newborns, there was a 3.8% incidence of congenital malaria and a cumulative incidence of acquired malaria of 3% at 12 weeks, 16% by 24 weeks, 24% by 36 weeks, and 38% by 48 weeks of age. Ninety-six percent of infants lost maternal antibody between 4 and 7 months, and most cases of asymptomatic malaria occurred among infants with detectable malaria antibody.

Although there were seasonal fluctuations in the overall incidence of parasitemia, Gilles [87] showed that the corrected rates were always lower for infants from birth to 2 months old than for infants 3 to 4 or 5 to 6 months old. He did not find differences in sleeping habits or in the amount of exposure to mosquitoes among infants in these age groups. In June to October, parasitemia was found in 10% of those from birth to 2 months old, 42% of those 3 to 4 months old, and 53% of those 5 to 6 months old; in May, parasitemia was found in 0% of infants from birth to 2 months old, 11% of those 3 to 4 months old, and 16% of those 5 to 6 months old. The rise in prevalence of parasitemia corresponded with a fall in the amount of fetal hemoglobin in the red blood cells [87]. The fact that cells containing fetal hemoglobin are poor hosts for the malarial parasite had been previously suggested by Allison [88,89] as one of the reasons for the selective advantage of sickle cell anemia and sickle cell trait in areas in which malaria is endemic. Although antibody is undoubtedly important in protecting newborns from malaria, Campbell and coworkers [6] and Reinhardt and associates [66] pointed out that antibody levels in infants from birth to 2 months old might be low or absent even when the mother has had parasitemia and placental infection. The presence of fetal hemoglobin in the red cells may serve as a source of protection for infants who do not derive high levels of antibody from their mothers.

Placental infection as a risk for congenital malaria was studied in 197 infants in Cameroon. Infants born to placenta-infected mothers were more likely to develop malaria than infants born to women without placental infection [90]. Rates of infant infection and parasitemia were not related to maternally derived malaria antibodies.

# CONGENITAL MALARIA

## Occurrence

There has been no consistently accepted definition of congenital malaria. Some have taken the position that parasites must be demonstrable in the peripheral blood of the infant during the first day of life; others have accepted cases that were confirmed within the first 7 days of life [81]. In areas in which malaria is endemic, infants are exposed to mosquitoes and may become infected by this route at a very young age. It may be difficult to distinguish congenital cases from acquired cases. However, a sufficient number of cases of congenital malaria have been reported from countries that are free of malaria, thereby eliminating the possibility of postnatal transmission, to establish the fact that the clinical onset of disease in a congenitally infected infant can be delayed for weeks and rarely even for months [59,60,91,92]. The prevalence of parasitemia in infants younger than 3 months was 0.7% among those born during the dry season in the rural part of Gambia, compared with 11.4% among those born during the wet season, which suggests that postnatal infection is a more common event than congenital malaria [65]. It is probable that IgG antibody transmitted from the mother to the infant is an important factor in determining whether parasites that reach the fetal circulation establish an infection. The presence of passively transferred antibody in the neonate may lengthen the incubation period beyond that which would be expected in the nonimmune host.

The frequency of placental infection varies according to the prevalence of malaria in the population, the vigor of measures of control, and the availability of nonprescription antimalarial drugs. However, among Nigerian women who did not receive antimalarial agents, three studies suggested that the frequency of infection of the placenta remained relatively stable over a 30-year period. In 1948 through 1950, Bruce-Chwatt [67] found that 20% of the placentas from 228 pregnancies were infected.

One (0.4%) of the 235 neonates had the trophozoites of *P. falciparum* in a peripheral smear obtained on the fifth day of life. In 1958 Cannon [63] found that 26% of the placentas were infected; in 1970 Williams and McFarlane [93] found that 37% of the placentas were infected. None of the cord blood samples of the infants in these latter studies contained parasites. In 1964 through 1965 in Uganda, Jelliffe found that 16% of the 570 placentas were infected but only one (0.18%) infant was infected at birth [69].

The studies of Kortmann [94], Reinhardt, and colleagues [62], and Schwetz and Peel [95] suggest that parasitemia in cord blood may be more common than had been previously believed and that the presence of parasites does not necessarily indicate that the infant will become infected. Reinhardt and colleagues [62] found 33% of 198 placentas to be infected. Thick smears of the cord blood were positive for 21.7% of the 198 infants and 55% of the infants of mothers who had had parasitemia during the pregnancy. Thin smears were negative for all 198 infants. Kortmann [94] was able to demonstrate parasites in 19.7% of the placentas of 1009 women but in only 3.8% of cord blood from their infants. Eleven infants who had parasites in their cord blood also had peripheral smears performed; parasites were demonstrable in the peripheral blood of only two (18%). Lehner and associates [94] found a 14.6% incidence of cord parasitemia and a 7.7% incidence of peripheral parasitemia among 48 newborns in Papua New Guinea. Whereas all maternal and cord samples had malaria antibodies, low levels of cord malaria antibody were found to correlate with cord parasitemia. Schwetz and Peel [96] demonstrated parasites in 6% of cord blood samples and 3.6% of peripheral blood samples of infants born to mothers in Central Africa. Because the rate of infection of the placenta was 74%, this study demonstrates that the placenta, although frequently infected, serves as a relatively effective barrier and that parasites infrequently reach the fetus. The relative importance of transplacental infection or transmission by transfer from mother to infant during labor as mechanisms by which the infant acquires malaria remains uncertain [95].

Despite massive involvement of the placenta, it is generally agreed that clinically apparent congenital infections are rare in areas in which malaria is endemic and levels of maternal immunity are high. Covell [82] reviewed cases of congenital malaria that had been reported up to 1950 and estimated the incidence at 16 (0.3%) infections per 5324 live births. This rate pertained to areas of the world in which malaria was endemic. For women having an overt attack of malaria during pregnancy, the rate of congenital infection was higher and was estimated to be 1% to 4% [82]. Congenital malaria is more common among infants of women who have clinical attacks of malaria during pregnancy than in those with chronic subclinical infections; however, congenital malaria may occur in infants of mothers who are asymptomatic throughout their pregnancies [81,92,97]. Often, parasitemia is not demonstrable in the mother; splenomegaly occurs frequently [72]. Congenital malaria is more common in infants of women who have immigrated to areas in which malaria is endemic than in women who have been raised to maturity in such areas because their levels of immunity are lower than those of the native population. Conversely, congenital malaria is also more common among women who immigrate from areas in which malaria is endemic to areas that are free of malaria. Loss of immunity results from lack of frequent exposure. Although rare, congenital malaria may also occur as a result of maternal infection by chloroquine-resistant *P. falciparum*. A number of reported cases of chloroquine-resistant congenital malaria in Africa and Indonesia responded to treatment with intravenous quinine [98–100].

## Clinical Presentation

Cases of congenital malaria have been identified in countries in which malaria is endemic and in countries in which it is not, including Great Britain and the United States. Most infants with congenital malaria have had the onset of the first sign or symptom when 10 to 28 days old [59,101,102]. However, onsets occurring as early as 8 hours and as late as 8 weeks of age have been reported [81,91,92,103–106]. Keitel and coworkers [60] described a case of malaria in a 15-month-old child who had been separated from her mother when 6 weeks old but who was breast-fed during this 6-week period. The infection was caused by *P. malariae*. The source of the mother's infection was probably contaminated needles and syringes used to inject heroin. The infant must have derived the infection from her mother because she had always lived in an area that was free of malaria. Hulbert [102] reviewed the 49 cases of congenital malaria reported in the United States since 1950 and found that the mean age at onset of symptoms was 5.5 weeks (range, 0 to 60 weeks) and that 96% of these children had signs or symptoms when 2 to 8 weeks old. There was no association found between age of symptom onset and *Plasmodium* species.

Most cases of congenital infection have occurred in infants of mothers who had overt attacks of malaria during pregnancy. However, Harvey and associates [92] and McQuay and colleagues [104] reported cases of congenital infection with *P. malariae* in which the mother had lived in an area that was free of malaria for 3 years or more. In these cases, it is likely that the mothers had had onset of their infection many years before their move from an endemic area.

The most common clinical findings in cases of congenital malaria are fever, anemia, and splenomegaly, which occur in more than 80% of cases [59,107]. The anemia, which may be accompanied by pallor, is associated with a reticulocytosis in about one half of the cases. Jaundice and hyperbilirubinemia are found in about one third of the cases. The direct or the indirect bilirubin level may be elevated, depending on whether liver dysfunction or hemolysis is the most important process in an individual case [59]. Hepatomegaly may occur but is less common than splenomegaly. Nonspecific findings include failure to thrive, poor feeding, regurgitation, and loose stools. In developing countries, when malaria occurs during the first few months of life, it is frequently complicated by other illness, such as pneumonia, septicemia, and diarrhea [105].

Of the 107 cases of congenital malaria summarized by Covell [82], 40% were caused by *P. falciparum*, 32% were caused by *P. vivax*, and 1.9% were caused by *P. malariae*. The clinical findings of congenital malaria are not distinguishable from the signs and symptoms of malaria that has been acquired by the bite of a mosquito. IgM antibody to *P. falciparum* was found in the cord blood of one infant [103]. The mother had probably had her first attack of malaria during that pregnancy and had high fever and parasitemia at delivery. Reinhardt and colleagues [62] found that the total IgM levels in the cord blood of infants of infected mothers were similar to those of infants of uninfected mothers. Although fever and parasitemia may occur within 24 hours of birth, hepatosplenomegaly and anemia at birth as a result of a chronic intrauterine infection have not been described. Normal red blood cells can cross from the maternal to the fetal circulation [62]. If parasitized cells cross, however, they must usually be destroyed by the immune defenses of the fetus and by the maternal antimalarial antibodies that have passed transplacentally.

## Treatment

Chloroquine is the drug of choice for sensitive strains of *P. falciparum* and for *P. malariae*. For these infections, chloroquine phosphate should be administered orally in an initial dose of 10 mg/kg of chloroquine base (maximum, 600 mg of base), followed in 6 hours by a dose of 5 mg/kg of chloroquine base (maximum, 300 mg of base). Subsequent doses of 5 mg/kg of chloroquine base should be given 24 and 48 hours after the first dose (maximum, 300 mg of base). Parenteral therapy consists of quinidine gluconate at a dose of 10 mg/kg as a loading dose (maximum, 600 mg) in normal saline given over 1 to 2 hours and then 0.02 mg/kg per minute until oral therapy can be given. Infections with *P. vivax* may be treated with chloroquine alone because sporozoite forms are not transmitted, and there is no exoerythrocytic phase in congenital infections; administration of primaquine is unnecessary. The treatment of transfusion-acquired infections is the same as that for congenital infections because there is no exoerythrocytic phase in these infections.

In serious infections in infants of mothers who may have been exposed to chloroquine-resistant strains of *P. falciparum*, alternate therapy should be considered. In adults, combinations of quinine, pyrimethamine, and a sulfonamide or quinine and tetracycline have been used with success [108]. Intravenous quinidine in combination with exchange transfusion has been used in a severe case of maternal *P. falciparum* malaria [109]. Intravenous quinidine or the combination of quinine and trimethoprim-sulfamethoxazole has been suggested for treatment of infants with resistant *P. falciparum* infection [110]. Intravenous quinine is no longer available in the United States, but in adults, oral quinine may be useful in less severe cases of chloroquine-resistant *P. falciparum*. Mefloquine is an oral antimalarial effective against most *P. falciparum* strains. Recommended therapy for *P. falciparum* infection in areas with known chloroquine resistance is variable, depending on ability to appropriately diagnose resistant *P. falciparum*, the percentage of parasitemia, signs of organ involvement (especially of the central nervous system), and other systemic manifestations of malaria. Severe malaria may require intensive care, and exchange transfusion may be necessary if the degree of parasitemia is greater than 10%. Sequential smears should be monitored to ensure adequacy of therapy. The treatment regimen of choice is quinine sulfate given as 25 mg/kg (maximum dose, 2000 mg) in three doses for 3 to 7 days in addition to tetracycline given as 5 mg/kg four times each day for 7 days (maximum individual dose, 250 mg). The risk of dental staining in children younger than 8 years of age must be weighed against the risks of malaria-related morbidity and mortality. Pyrimethamine-sulfadoxine and mefloquine are not licensed for use in infants and pregnant women by the U.S. Food and Drug Administration; data regarding use of mefloquine during pregnancy do not indicate a risk of adverse outcomes during pregnancy. Inadvertent use of mefloquine during the first trimester of pregnancy should be reported to the Centers for Disease Control and Prevention Malaria Center (phone: 770-488-7760). Current recommendations regarding treatment can also be obtained from the Malaria Branch, Centers for Disease Control and Prevention, Atlanta. Recent clinical trials using an artemisinin combination treatment compared with intravenous quinine in Asian adults have demonstrated improved outcomes; trials among African populations are underway but consideration for use among pregnant women have been hampered by safety concerns in animal studies [54].

## Prevention

Because malaria chemoprophylaxis may not be 100% effective, decreasing or eliminating exposure to mosquitoes is an important strategy for preventing malaria during pregnancy. Exposure to mosquitoes should be avoided by use of mosquito netting around beds, wire mesh screening on windows, insecticides, and mosquito repellants.

Although the possible toxicity of administering prophylactic antimalarial agents to women during pregnancy has been much discussed, controlled trials have shown that there is little risk and much to gain from such a practice. Treatment only for identified cases of maternal malaria, rather than the administration of malaria prophylaxis, failed to reduce the incidence of malaria-related low birth weight because only 12 of 65 women who had plasmodial pigmentation of the placenta had symptoms leading to an antenatal diagnosis of malaria [98–100,111]. Morley and associates [112] showed that administration of a prophylactic monthly dose of 50 mg of pyrimethamine during pregnancy resulted in improved maternal weight gain and in an increase in the mean birth weight of 157 g compared with administration of antimalarial drugs only for febrile episodes. Pyrimethamine prophylaxis is avoided in pregnant women because of concern that this dihydrofolate reductase inhibitor may cause abnormalities by interference with folic acid metabolism. Congenital defects have occurred in the offspring of animals ingesting pyrimethamine during pregnancy [113]. One possible case of pyrimethamine teratogenicity in a human fetus has been described [114], and evidence of embryo

resorption has been documented in pregnant Wistar rats given sulfadoxine-pyrimethamine [115].

A retrospective review of 1627 reports of women exposed to mefloquine before or during pregnancy revealed a 4% prevalence of congenital malformations among infants of these women, reportedly similar to that observed in the general population [116]. A second report demonstrated a high rate of spontaneous abortions, but not congenital malformations, among 72 female U.S. soldiers who inadvertently received mefloquine during pregnancy [117]. Sufficient data do not exist to recommend the use of mefloquine in pregnant women, although its use in these women may be considered when exposure to chloroquine-resistant *P. falciparum* is unavoidable. The dose is 250 mg of the salt taken orally once each week, beginning 1 week before travel and ending 4 weeks after the last exposure. The combination of pyrimethamine and sulfadoxine for prophylaxis against chloroquine-resistant strains of *P. falciparum* is no longer recommended because the risk of Stevens-Johnson syndrome or neutropenia outweighs the potential benefit. Prophylaxis with chloroquine and proguanil is an alternative if a pregnant woman from a nonendemic area must risk exposure to resistant *P. falciparum* [118].

Chloroquine alone also has been used as prophylaxis during pregnancy and has been shown to be of benefit [119]. Gilles [64] found that parasitemia developed in more than 75% of pregnant women who received no prophylactic drug or who received folic acid but no antimalarial drugs. Sixty-three percent of these women developed anemia at 16 to 24 weeks' gestation. In contrast, only 2 (17%) of 12 pregnant women who received a dose of 600 mg of chloroquine base followed by a weekly dose of 25 mg of pyrimethamine developed parasitemia, and only one developed anemia. Although anemia may be an important cause of low birth weight, as Harrison and Ibeziako maintained [120], malaria appears to be an important cause of anemia in pregnant women [120,121].

Chloroquine and the other 4-aminoquinolines, such as amodiaquine and hydroxychloroquine, have similar activities and toxicities. The safety of administering chloroquine during pregnancy has been questioned. The usual recommendation for prophylaxis is 300 mg of chloroquine base once each week. Hart and Naunton [122] attributed the abnormal outcome of four pregnancies in a single patient to the administration of chloroquine during the pregnancies. This patient, who had systemic lupus erythematosus (SLE), took 150 to 300 mg chloroquine base daily. Two of the children who had had intrauterine exposures to chloroquine had severe cochleovestibular paresis and posterior column defects. Another had a Wilms tumor and hemihypertrophy. The fourth pregnancy ended in a spontaneous abortion at 12 weeks' gestation. As pointed out by Jelliffe [123] and Clyde [124], the dose given to this pregnant patient was three to seven times higher than the dose recommended for prophylaxis against malaria. Two other studies reported pregnancy outcomes after exposure to antimalarials. Parke [125] described 14 pregnancies among eight patients with SLE who took chloroquine or hydroxychloroquine during pregnancy. Three pregnancies ended in spontaneous abortion or neonatal death during periods of increased SLE activity; of the remaining 11 pregnancies, 6 were normal full-term deliveries, 1 ended in stillbirth, and 4 ended in spontaneous abortion. No congenital deformities occurred. Levy and coworkers [126] reviewed the cases of 24 women who took chloroquine or hydroxychloroquine during a total of 27 pregnancies. Eleven women had SLE, three had rheumatoid arthritis, and four were taking malaria prophylaxis. There were 14 normal deliveries, 6 abortions attributed to severe underlying disease or social conditions, 3 stillbirths, and 4 spontaneous abortions. No congenital abnormalities were identified. The risk of poor outcome was higher among women with connective tissue disease, for which chloroquine and hydroxychloroquine doses are much higher than for malaria prophylaxis. Despite widespread use of weekly doses of chloroquine in pregnant women, teratogenic effects have not been confirmed in controlled trials [127].

The consequences of an attack of malaria during pregnancy are serious. Hindi and Azimi [91] described a woman who became pregnant while living in Nigeria but who stopped taking prophylactic doses of pyrimethamine at the onset of pregnancy. At 6 months' gestation, she had a febrile illness and was treated with chloroquine for 2 weeks. At 8 months' gestation, she had a second attack of malaria and was delivered of an infant who was 4 weeks premature and small for gestational age. The infant developed malaria during the first few weeks of life and was treated with chloroquine. The total exposure of this infant to chloroquine would have been less if the mother had been taking it weekly in prophylactic doses.

Women living in or returning from areas in which malaria is endemic should continue to take prophylactic antimalarial agents. Although primaquine is not known to have teratogenic effects, experience with its use during pregnancy is limited; it is therefore recommended that treatment with primaquine to eradicate the exoerythrocytic phase in *P. vivax* infections be deferred until after delivery [114,128].

Some investigators think the widespread use of prophylaxis may lower the level of maternal immunity and increase the severity of cases of malaria seen in children who are younger than 1 year. There is no evidence that administration of antimalarial drugs prophylactically to pregnant women has changed the expected incidence of infection during the first few months of life.

Because of the tremendous global burden of disease imposed by malaria infections, a key initiative in the prevention of malaria is the emphasis on development of malaria vaccines. The cloning of the *P. falciparum* receptor protein, which allows red blood cell attachment, should facilitate the development of a malarial vaccine [129,130]. Vaccine candidates are in development, but no effective vaccine will be immediately available [131–133]. Other techniques for malaria prevention include use of improved chemoprophylactic regimens and development of animal models for malaria infection in which to test vaccines and antimalarial drugs. A rhesus monkey model mimicking human infection after exposure to *Plasmodium coatneyi* has been tested with potential for use in animal studies [134]. Recommendations for malaria prophylaxis in pregnant women may be obtained from the Malaria Branch, Centers for Disease Control and Prevention, Atlanta.

## SCHISTOSOMIASIS

Schistosomiasis (i.e., bilharziasis) contributes to infertility by causing sclerosis of the fallopian tubes or cervix [135]. It is estimated that 9 to 13 million women may be afflicted by genital schistosomiasis in Africa alone [136]. The placenta usually does not become infected until the third month of pregnancy or thereafter [137]. Although the frequency of placental infection is as high as 25% in endemic areas, the infestations are light and cause little histologic reaction [137,138]. In their study of the impact of placental infection on the outcome of pregnancy, Renaud and coworkers [137] concluded that there was little evidence that the size or weight of the infant was affected and that placental bilharziasis was not an important cause of intrauterine growth retardation or prematurity.

## TRICHOMONAS VAGINALIS

Infection of the vagina of the pregnant woman with *Trichomonas vaginalis* is not uncommon, but no adverse effect on the fetus has been documented [139–141]. There are six reports in the literature of *T. vaginalis* recovered from a respiratory source among neonates, all with respiratory illness whose viral and bacterial cultures revealed no other pathogens, but a causal relationship was not certain [142,143]. During the first 2 weeks of life, female newborns may be particularly susceptible to infection because of the influence of maternal estrogens on the vaginal epithelium. By 3 to 6 weeks of age, the vaginal pH is no longer acid [144]. *T. vaginalis* has been found in 0% to 4.8% of sequentially studied female newborns [144–146]. Among infants younger than 3 weeks who had vaginal discharges, *T. vaginalis* was the probable cause of the discharge in 17.2% [147]. In addition to causing a vaginal discharge [148], infection of the newborn with *T. vaginalis* may aggravate candidal infections and may be associated with urinary tract infections [144]. In most infants, the white blood cells found in the urine originate from the vagina rather than from the bladder [149]. However, several reports suggest that a bacterial urinary tract infection can be present concomitantly [150,151]. In symptomatic cases, metronidazole has been used at a dosage of 500 mg twice daily or 15 mg/kg/day divided in 3 doses for 5 to 7 days [144,149,152].

## TRICHINOSIS

Prenatal transmission of trichinosis from mother to infant is rare. Four larvae, however, were found in the diaphragm of a fetus by Kuitunen-Ekbaum [153]. No evidence of infection with trichinosis was found in 25 newborns studied by McNaught and Anderson [154]. Despite this, *Trichinella spiralis* has been found in the placenta, in the milk of nursing women, and in the tissue from the mammary gland [155]. In 1939, Hood and Olson [156] found *T. spiralis* in pressed muscle preparations from 4 (8.3%) of 48 infants from birth to 12 months of age. Although transplacental transmission is rare, *T. spiralis* is present in the placenta of women with acute trichinosis and can be passed to the infant by means of breast milk.

## BABESIOSIS

*Babesia microti* is a tick-borne protozoan that infects erythrocytes and causes a malaria-like illness. Most cases in the United States have occurred in the Northeast. Raucher and colleagues [157] described a *B. microti* infection in a pregnant woman that began in the 19th week of gestation; the infant was born at term without evidence of infection. Ten neonatal cases have been reported in the literature. Of those, seven were transfusion-related, two were congenital, and one was secondary to tick transmission [158].

## PNEUMOCYSTIS JIROVECI

*P. jiroveci* is an infectious agent with a history. In 1988, DNA analysis demonstrated that *Pneumocystis* was not a protozoan, but a fungus [159,160]. Subsequent DNA analysis has led to the change in nomenclature of *P. carinii* to *P. jiroveci*, a name chosen in honor of the parasitologist Otto Jirovec, who is credited by some with the original description of this organism [159,160]. *P. carinii* as a fungus has been defined based on molecular analysis [161,162]. Previous controversy over the classification *Pneumocystis* existed because of the difficulty in cultivating and further characterizing the biochemical nature of the organism. Questions remained until polymerase chain reaction techniques established that *P. jiroveci* was not found in lung samples from any other mammals [163]. However, genetic analysis clearly demonstrated differences between human and nonhuman *Pneumocystis* isolates [164]. This organism is covered in detail in Chapter 34: "Pneumocystis and Other Less Common Fungal Infections."

CHAPTER 33

# CANDIDIASIS

**Catherine M. Bendel**

CHAPTER OUTLINE

## INTRODUCTION

*Candida* species are important pathogens in the neonate. Over the past 2 decades, there has been a significant increase in the incidence of systemic candidiasis in neonatal intensive care (NICU) patients, particularly among the very low birth weight (VLBW; birth weight ≤1500 g) infants [1–5]. Infections range from superficial colonization to widely disseminated, life-threatening disease. Unfortunately, the most dramatic rise has been in the incidence of invasive or systemic candidiasis. With improvements in technology, more aggressive approaches to the treatment of VLBW infants have become the standard of care. Concomitantly, there has been an increase in risk factors for neonates to develop candidemia, most notably the prolonged use of indwelling intravascular catheters and multiple courses of broad-spectrum antimicrobial agents [6,7].

*Candida albicans* remains the most frequently isolated yeast species among infected neonates; however, the incidence of infection with other species, particularly *Candida parapsilosis* and *Candida glabrata*, has increased exponentially over the past 10 years [8–12]. The importance of *Candida* as a pathogen in VLBW infants is reflected by a mortality rate approaching 30% in this fragile group of immunocompromised patients, even among those who receive appropriate antifungal therapy, and a significant accompanying morbidity among survivors [5,13,14].

## EPIDEMIOLOGY AND TRANSMISSION

Infections with *Candida* species afflict immunocompromised hosts, diabetics, trauma patients, postoperative patients (particularly after gastrointestinal procedures), and neonates; and are most often nosocomially acquired [1,15,16]. The SENTRY Antimicrobial Surveillance Program, monitoring bloodstream infections (BSI) due to both *Candida* spp. and bacteria among all patients in participating hospitals, reports *Candida* species as the fourth most common nosocomial BSI overall, with *C. albicans* the most common single pathogen [15]. In neonates, the numbers are equally striking. Approximately 1.4% of early-onset neonatal infections result from *Candida* species, for late-onset sepsis the incidence varies from 2.6% to 16.7% among the very low birth weight infants (VLBW, ≤ 1500 g) and up to 20% for the extremely low birth weight infants (ELBW, ≤ 1000 g) [5,6,17–19]. Among hospitals participating in the Neonatal Institute of Child Health and Human Development (NICHD) Neonatal Research Network, *C. albicans* was the third most frequent single organism isolated among all pathogens responsible for late onset sepsis [20].

Although *C. albicans* remains the leading cause of disseminated fungal infection among hospitalized patients, the isolation of other yeast species, including *C. glabrata*, *C. parapsilosis*, *Candida tropicalis*, *Candida krusei*, *Candida lusitaniae*, *Candida dubliniensis*, and even *Saccharomyces cerevisiae*, is occurring more frequently [4,9,15,21]. Table 33–1 displays the relative distribution of *Candida* species recovered from the bloodstream of all NICU patients in the National Nosocomial Infection Surveillance (NNIS) system compared with the overall population reported in the SENTRY program [9,15]. Among neonates *C. albicans* and *C. parapsilosis* remain the predominant species compared with adults in whom the predominant species isolated are *C. albicans*, *C. parapsilosis*, and *C. glabrata*, each of which accounts for approximately 15% of yeast infections [12]. Historically, *C. albicans* has been considered the most virulent species. A retrospective study of neonatal candidiasis in the 1980s revealed a 24% mortality rate among infants infected with *C. albicans*, but no deaths among those infected with *C. parapsilosis* [11]. Later case series have shown an increase in infections with non-*Candida albicans Candida* (NCAC) species and mortality for neonates infected with *C. glabrata* and *C. parapsilosis* equivalent to that for *C. albicans* infections [8,22–24]. Although *C. albicans* may be responsible for more infections than NCAC species, almost all *Candida* species have been implicated in disease and any candidal infection in the neonate can be life threatening.

*Candida* species are commensal organisms, colonizing the human skin, gastrointestinal tract, and female genitourinary tract [16,25–27]. Studies evaluating gastrointestinal tract colonization document approximately 5% of neonates are colonized with *Candida* on admission to the NICU; up to 50% are colonized by the end of the first week and almost three fourths by the end of the first month of life [25,28–30]. A variety of *Candida* species colonize the human gastrointestinal tract, including *C. albicans*, *C. tropicalis*, *C. glabrata*, and *C. parapsilosis* in neonates [28,30,31]. More than one species may be recovered from a single host, but there is usually a predominant colonizing species [32]. The *Candida* strain colonizing the infant most often is acquired by vertical transmission from the maternal vaginal mucosa after passage through the birth canal [32–34]. Using molecular typing techniques, vertical transmission of *C. albicans*, *C. parapsilosis*, and *C. glabrata* has been documented in term and preterm infants [32,33,35]. Heavy maternal colonization or maternal *Candida* vaginitis is an important risk factor for efficient transmission, resulting in increased neonatal colonization and the potential for disease [33,34,36]. Intrauterine fetal infections occur rarely, but they have been attributed to ascending infection from the vagina of the mother and transplacental transmission [37,38]. Breast-feeding can result in transmission of yeast present on the maternal skin to the infant's oral mucosa, and *Candida* species have been recovered from expressed breast milk [39]. Candidal mastitis increases the risk of transmission. Perinatal transmission can result in colonization, congenital candidiasis, or mucocutaneous infections in the term infant, whereas the result can be disseminated or systemic candidiasis in the preterm infant [40,41].

Although maternal vertical transmission is more common, acquisition of *Candida* from care providers may occur and is the primary mode of transmission for *C. parapsilosis* [22,32,33]. In one study evaluating 19 mother-infant pairs; no maternal reservoir could be demonstrated among infants colonized with *C. parapsilosis* [32]. Although different from the typical transmission route seen with *C. albicans* and *C. glabrata* (the two species found most often in the maternal gastrointestinal or genitourinary tract), this observation is not surprising. Given that maternal gastrointestinal or genitourinary colonization with *C. parapsilosis* is uncommon, the risk of perinatal exposure and transmission is equally low [42]. After birth, NICU personnel, rather than the mother, have the greatest contact with the preterm or sick infant. Because *C. parapsilosis* is the most common *Candida* species recovered from the hands of health care providers, transmission can be expected and may be a contributing factor to the increased incidence of *C. parapsilosis* catheter-associated infections in high-risk neonates [43,44].

Colonization is important in the development of disease because the *Candida* strain recovered in infection usually is identical to the colonizing strain [45–47]. Disseminated infections result from translocation across the gastrointestinal tract epithelium of commensal *Candida* species [16,45,48]. However, colonization does not inevitably lead to disease, and infection does occur in the absence of apparent colonization [49]. Direct transmission of *Candida* to NICU infants has been documented from exogenous yeast carried by hands of hospital personnel or found on equipment [44,50,51]. This emphasizes the need for proper hand hygiene among health care workers in the NICU—although most of the antimicrobial soaps available are not fungicidal, and it is primarily the mechanical action of washing that decreases the burden of *Candida* species present [52,53]. Vaudry and colleagues described an outbreak of candidemia in seven infants without central intravascular catheters, and molecular typing of the *C. albicans* strains grouped the isolates into two cohorts corresponding with the timing of infections and the geographic location of babies in the nursery [54]. The use of intravascular pressure-monitoring devices has been associated with *C. parapsilosis* fungemia in an NICU [55]. *Candida* infections have resulted from retrograde administration of medications by multiple-use syringes in infants receiving total parenteral nutrition; in these cases, the responsible organisms, *C. albicans*, *C. tropicalis*, and *C. parapsilosis*, were isolated from the blood of the infants and the medication syringe [44]. The outbreak subsided with a change to single-use syringes. A nursery outbreak of *Candida guilliermondii*, a typically nonpathogenic NCAC, was traced to contaminated heparin vials used for flushing needles for blood drawing [55]. All of these examples point to the ubiquitous nature of *Candida* species and the need for stringent infection control practices on the NICU to decrease the acquisition of nosocomial infections [56,57].

## MICROBIOLOGY

The name *Candida* comes from the Latin term candidus, meaning "glowing white," which refers to the smooth, glistening white colonies formed by these yeasts when grown on culture media. The taxonomy of the genus *Candida* is somewhat challenging and incomplete because of the reclassification of certain species (e.g., Torulopsis glabrata has been correctly identified as *C. glabrata*) and the discovery of new species such as *C. dubliniensis*, *Candida orthopsilosis*, and *Candida matepsilosis* (the last two previously classified as part of the *C. parapsilosis* complex) [58–60]. Previously used terms, such as Fungi Imperfecti, *Oidium*, and *Monilia*, are no longer used in classifying the

genus *Candida*. Fungi Imperfecti, or Deuteromycetes, refers to the class of fungi that reproduce asexually. This was the prevailing theory regarding *Candida*; however, a teleomorph, or sexual stage, has been described for certain *Candida* species (e.g., *C. krusei*, *C. guilliermondii*), eliminating this characteristic as a useful tool in classification [61]. *Oidium* and *Monilia* were 19th century terms that are no longer used to refer to the genus *Candida*, although the term monilial is still commonly used to describe the characteristic rash observed in cutaneous *Candida* infections [61,62].

Although more than 150 species of *Candida* have been described, relatively few species infect humans. Most exist as environmental saprophytes, and more than one half the *Candida* species described cannot even grow at 37° C, making them unlikely candidates to be successful human pathogens [63]. *C. albicans* is the most prevalent species causing human disease, but other pathogenic species include *C. parapsilosis*, *C. glabrata*, *C. tropicalis*, *Candida pseudotropicalis*, *C. paratropicalis*, *C. krusei*, *Candida lusitaniae*, *C. guilliermondii*, *C. dubliniensis*, and *C. orthopsilosis*. The primary pathogens among neonates are *C. albicans* and *C. parapsilosis* (see Table 33–1).

Members of the genus *Candida* are ubiquitous and form a heterogeneous group of eukaryotic, dimorphic, or polymorphic organisms. All *Candida* species grow as yeast cells or blastoconidia under general culture conditions between 25° C and 35° C, and growth is augmented by increased sugar or fat content in the media. Yeast cells are approximately 2 to 10 μm in the largest dimension, round to oval, and reproduce by budding. *C. albicans* is among the larger yeast at 4 to 6 × 6 to 10 μm, whereas *C. glabrata* and *C. parapsilosis* are among the smallest at 1 to 4 μm × 2 to 9 μm and 2 to 4 × 2 to 9 μm, respectively [61]. Figure 33–1, *A* shows *C. albicans* single blastoconidia and budding yeast cells. Most members of the genus also produce a filamentous form: pseudohyphae (see Fig. 33–1, *B*) or true hyphae (see Fig. 33–1, *C*). *C. glabrata* is the only pathogenic species that does not produce filamentous forms, existing exclusively as blastoconidia [61]. *C. parapsilosis* forms pseudohyphae but not true hyphae. Only *C. dubliniensis* and *C. albicans* form true hyphae (see Fig. 33–1, *C*), distinguishing these two species as polymorphic rather than dimorphic. Formation of a germ tube precedes the development of true hyphae, and this change in morphology can be induced by growth in serum or other specialized media or by incubation at 37° C. The clinical diagnostic microbiology laboratory has exploited this distinction by use of the germ tube formation test to rapidly identify *C. albicans* over other *Candida* species [64].

The ability to form true hyphae is considered one of the prime virulence factors for *C. albicans* [65]. Microscopic examination of infected human and animal tissue usually demonstrates the presence of *C. albicans* hyphae [66–70]. Conversely, nonfilamentous yeast, such as *S. cerevisiae*, rarely cause human disease, and genetically altered strains of *C. albicans*, which cannot filament normally, are generally less virulent in animal models of fungemia. [71–75] Other commonly recognized virulence factors for *C. albicans* include the production of proteinases and phospholipases, hydrophobicity, the presence of various surface molecules (e.g., receptors, adhesions), and the production of biofilm (which may be particularly important in catheter-associated infections) [66,70,74,76–80].

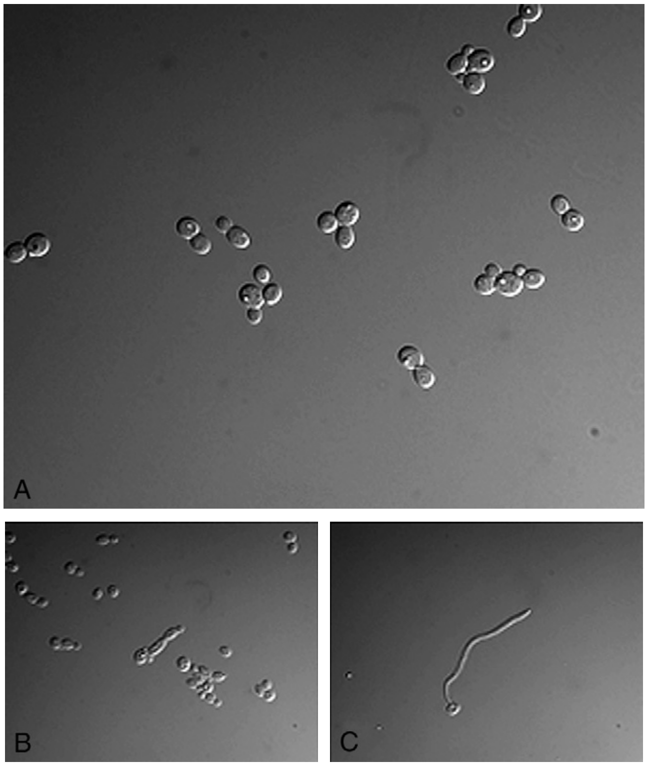

**FIGURE 33–1** Light microscopy photographs of *Candida albicans blastoconidia* or yeast cells **(A)**, pseudohyphae **(B)**, and true hyphae **(C)**. *(Courtesy Cheryl A. Gale, MD, University of Minnesota Medical School, Minneapolis.)*

A variety of surface molecules of *C. albicans* are responsible for modulating epithelial adhesion by interacting with host ligands on the epithelial or endothelial surface [71,81,82]. Ligands include sugar residues on human buccal epithelial cells and a wide variety of extracellular matrix proteins, such as fibronectin, fibrinogen, types I and IV collagen, laminin and the complement components iC3b and C3d [83]. Reciprocally, human cells recognize yeast cell ligands via pattern recognition receptors (PRRs), such as Toll-like receptors (TLR) or the β-glucan receptor (βGR) Dectin-1 [84,85]. In tissue culture assays, *C. albicans* is more adherent than other *Candida* species to every form of human epithelium and endothelium available, including cultured buccal epithelium, enterocytes (adult and fetal), cervical epithelium, and human umbilical vein endothelial cells [36,86–88]. The adhesive molecules responsible for epithelial and endothelial adhesion may also facilitate binding between individual *Candida* cells and the subsequent development of “fungus balls” found in infected organs [83,89]. No single adhesin molecule is completely responsible for the adherence of *C. albicans* to human epithelium, and multiple methods of interacting with the host surface are postulated for this commensal organism [83]. *C. albicans* and *C. parapsilosis* both adhere well to the surface of catheters and, in the process, form a biofilm—although the biofilms formed by *C. albicans* are more dense and complex than

those formed by other *Candida* spp [90–93]. The biofilm microenvironment promotes fungal growth with hyphal transformation and may confer relative drug resistance because of poor penetration of antimicrobial agents into this mass of extracellular matrix, yeast cells, and hyphae [78,94]. In vitro studies of *C. albicans* biofilms document the development of fluconazole resistance within 6 hours of formation [91]. Biofilm formation is associated with persistent fungemia and with co-infection by nosocomial bacterial pathogens, such as *Staphylococcus* species [90,95,96]. *Candida* spp. induce a strong TLR-mediated pro-inflammatory response in cultured oral epithelial cells resulting in profound IL-8 secretion [97]. In addition, the βGR dectin-1 and toll-like receptors TLR2 and TLR4 (thought to be the main receptors for the innate immune system recognition of *C. albicans*) appear to work synergistically, with dectin-1 amplifying TNF-α production via the TLR pathway [84]. The ability to adhere to human epithelium and endothelium (and to itself and catheters) resulting in microenvironmental changes, is a significant virulence factor setting *C. albicans* apart from other *Candida* species, and may be a prominent reason for the increased frequency with which *C. albicans* is found colonizing the host and causing disease at epithelial and endothelial sites.

Virulence factors of other *Candida* species have not been well studied. A fibronectin receptor that facilitates epithelial adhesion has been described in *C. tropicalis* [98,99]. *C. glabrata* colonizes the gastrointestinal tract, but no specific virulence factors have been identified in this nonfilamentous *Candida* species [100]. *C. parapsilosis* has been recovered from the alimentary tract of neonates, but no work has been done to implicate or exclude the gastrointestinal tract as a possible source of infection among neonates, and no specific virulence factors have been identified in this *Candida* species [24,28,35,93]. *C. glabrata* and *C. parapsilosis* produce biofilms; however, this area has not been well investigated for either of these pathogenic NCAC species [78,93]. Overall *Candida* species exhibit relatively low-level virulence factors compared with organisms that typically cause disease in an immunocompetent host. Candidal virulence factors serve to differentiate the more virulent from the less virulent *Candida* species, rather than to distinguish *Candida* from other more pathogenic microbes.

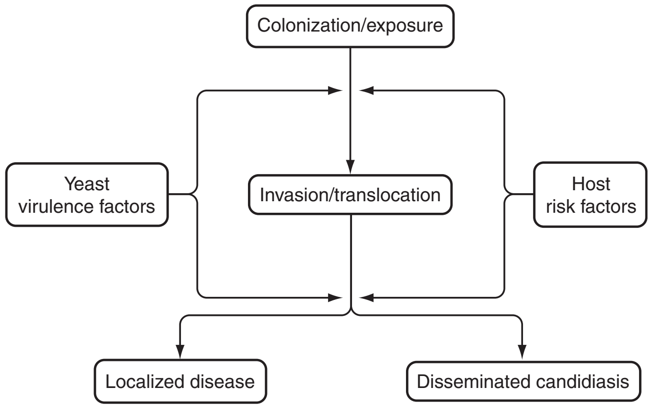

**FIGURE 33–2** The pathogenesis of neonatal candidiasis follows a pathway from colonization to infection, modified by multiple host factors and yeast virulence factors.

**TABLE 33–2** Host Factors Enhancing Risk for Candidiasis in Neonates

| |
|---|

## PATHOGENESIS

The pathogenesis of invasive candidiasis involves a common sequence of events in all at-risk hosts: colonization, resulting from adhesion of the yeast to the skin or mucosal epithelium (particularly the gastrointestinal tract); penetration of the epithelial barriers; and locally invasive or widely disseminated disease. Dissemination to deep visceral organs results from hematogenous spread [101]. However, not every colonized patient develops a *Candida* infection. The unique combination of host factors and yeast virulence mechanisms results in the persistence of benign colonization or the progression to infection among high-risk neonatal patients, as outlined in Figure 33–2. Yeast virulence factors were described in the preceding section. Host risk factors, listed in Table 33–2, are potentially more important in the development of neonatal candidal infections [14,48,102]. Limitation of exposure to all predisposing conditions for candidal infection is highly desirable but rarely feasible, especially in the VLBW infant.

Indiscriminate, frequent, or prolonged use of broad-spectrum antimicrobial agents, resulting in alterations of the normal skin and intestinal microbial flora, allows for overgrowth of the colonizing strain of *Candida* and a concomitant increased risk for translocation and hematogenous spread [48]. The greater the density of organisms in the neonatal gastrointestinal tract, the greater is the chance of dissemination [103]. High levels of *Candida* colonization found in certain nurseries are linked to patterns of antibiotic usage, including a particularly strong association with third generation cephalosporin use [8,47,104].

The immunocompromised state predisposes an infant to candidal infection, whether caused by the developmentally immature immune system of the newborn, a congenital immunodeficiency, or the immunosuppression accompanying steroid therapy. No single defect in the immune system appears to be solely responsible for an increased susceptibility of premature neonates to candidal infections. Healthy adults have circulating IgG antibodies to *Candida* antigens, which effectively opsonize the organism and activate the alternative complement pathway [105–107]. Neonatal IgG levels depend on maternal exposure to the yeast accompanied by transplacental transmission of candidal antibodies, and the ability for the infant to respond to a new challenge with a *Candida* species, which may be slow and inadequate [105,108,109]. Polymorphonuclear leukocytes ingest and kill *Candida*; therefore, neutropenia is an important risk factor [70,110]. Disseminated candidiasis in neonates is associated with the intravenous administration of dexamethasone and hydrocortisone [111–113]. Steroid therapy results in immunosuppression and may have direct effects on colonization and translocation from the gastrointestinal tract. In vitro studies have shown that *C. albicans* is more adherent to monolayers of cultured enterocytes treated with dexamethasone than to untreated control monolayers, whereas mice injected with dexamethasone demonstrate higher levels of gastrointestinal tract colonization with *C. albicans* and increased rates of dissemination to the kidney [68]. Steroids may have a direct effect on the yeast by regulation of gene expression, including multidrug resistance genes and other modulators of virulence [114]. The presence of indwelling catheters is a significant predisposing risk factor for neonatal candidiasis. Endotracheal tubes, urinary catheters, peritoneal catheters, chest tubes, mediastinal tubes, and ventriculoperitoneal shunts can all become infected, but the greatest risk lies with intravascular catheters, particularly central venous catheters [5,50]. All catheters in the vascular space for more than a day begin to develop a thrombin sheath with a matrix-like substance, providing an optimal site for accumulation of micro-organisms [76]. *Candida* species adhere extremely well to the inert surface of the catheter, and electron microscopy studies have shown that *Candida* species are able to burrow into the catheter and form a surrounding biofilm [76,82,115]. This sequence results in a unique microenvironment, providing a barrier to host defenses and offering optimal conditions for growth and proliferation of the *Candida* organism, often resulting in the development of an infected mural thrombus extending from the tip of the catheter [116–118]. The "fungal mass" adherent to the catheter can then serve as a source for persistent fungemia or embolic spread of *Candida* species to distant organs [1,48]. The original source of the yeast that "sticks" to the line may be from hematogenous spread of endogenous gastrointestinal tract *Candida* strains or from nosocomial transmission through placement or handling of the catheter itself [44,54,101]. Use of the catheter for hyperalimentation is an additional risk, especially with the infusion of high dextrose-containing total parenteral solutions and intralipids [5,6,48,119]. Any compromise of epithelial barriers can predispose the neonate to candidal infections. Abdominal surgery and cardiac surgery are associated with an increased risk for disseminated candidiasis, especially among term infants [48,95]. Necrotizing enterocolitis (NEC) is strongly associated with *Candida* fungemia [5,16,120]. The loss of mucosal integrity after mesenteric ischemia and NEC provides a portal of entry for the dissemination of endogenous gastrointestinal flora [101]. Spontaneous intestinal perforation, occurring most often in the extremely preterm infant, is highly associated with candidemia [19,121]. As with any nosocomially acquired organism, prolonged hospitalization is a significant risk factor for the development of candidiasis [5].

Prematurity is a key risk factor for candidiasis, especially infants born at less than 28 weeks' gestation or VLBW neonates [4,5,48]. With improvements in technology, the current standard of care in the NICU includes an aggressive approach to the treatment of VLBW infants such that life for an extremely premature infant combines nearly all the risk factors for candidiasis in one patient [48,122]. The premature infant is born with immature epithelial barriers and an immature immune system. The skin and mucosal epithelium of these very tiny infants are minimally protective, readily breaking down with exposure to air and routine nursing procedures [123]. Preterm infants have the lowest levels of circulating maternal IgG of all neonates, having lost the opportunity for transplacental transfer that occurs during the third trimester of pregnancy [124]. Even if specific anti-*Candida* IgG is present, opsonization and complement activation are diminished [125]. Complement levels are extremely low in preterm infants, with biochemical abnormalities of C3 resulting in inadequate activation of this pathway for fighting infections [126]. Neutropenia is common among infants born at less than 28 weeks' gestation [127]. Virtually every premature infant begins life with a course of empirical broad-spectrum antibiotics, leading to an interruption in the process of establishing the normal gastrointestinal microflora and the potential for unchecked proliferation of *Candida* [50,128,129]. Endotracheal and intravascular catheters are true lifelines for the VLBW premature infant needing respiratory, inotropic agent, and nutritional support. Because venous access is often difficult to obtain and maintain in these infants, intravascular access lines are not automatically rotated and frequently remain in place for weeks. Even the fairly healthy VLBW infant often displays feeding intolerance that can require prolonged central total parenteral nutrition (TPN) rather than enteral feeds [5]. As reported by the National Institute of Child and Human Development (NICHD) Neonatal Research Network, the adjusted odds ratio for any episode of late-onset sepsis is 3.1 in VLBW infants receiving TPN for 8 to14 days, rising to 4.0 for an infant receiving TPN for more than 22 days [20]. Saiman and colleagues reported odds ratios for developing candidemia of 2.93 for infants less than 1000 g receiving TPN more than 5 days and 2.91 for IV intralipid use for more than 7 days [48]. Unfortunately, NEC may also accompany feeding intolerance, leading to an additional risk for disseminated candidiasis [130–132]. Corticosteroid use is also common in these patients [132]. Multiple reviews report that almost one half of the infants with a birth weight of less than 750 g are postnatally exposed to

corticosteroids: hydrocortisone used to treat hypotension; dexamethasone, methylprednisolone or hydrocortisone used for severe lung disease [112,132,133]. Hyperglycemia and hyperlipidemia are common in these immature patients receiving TPN, steroids, or both [113,119]. Prolonged length of stay is the rule rather than the exception for the NICU infant, with or without a nosocomially acquired infection. The average corrected gestational age at discharge from the NICU is between 35 and 36 weeks, and the average NICU hospitalization is approximately 62 days; however, the length of stay to achieve 36 weeks' gestational age is even longer for the infant born at less than 28 weeks' gestation [20,48]. Each of these factors especially in combination, make the VLBW preterm infant an extremely high-risk candidate for the development of candidiasis.

## PATHOLOGY

The tissue pathology observed in *Candida* species infections depends on the site of involvement and the extent of invasion or dissemination. Histologic evaluation of mucosal or epithelial lesions reveals superficial ulcerations with the presence of yeast and filamentous forms of *Candida* species, including a prominent polymorphonuclear (PMN) leukocyte infiltration [134]. Extremely low birth weight (ELBW; birth weight $\leq$ 1000 g) infants can develop invasive fungal dermatitis with erosive lesions; biopsy of these lesions reveals invasion of fungal elements through the epidermis into the dermis [123,134]. In disseminated neonatal infections, *Candida* species can invade virtually any tissues. Microabscesses are commonly found in the kidney, retina, and brain, but they also have been described in the liver, spleen, peritoneum, heart, lungs, and joints [11,134–137]. When *C. albicans* is the infecting organism, abscesses contain a predominance of hyphal elements with a significant accompanying infiltration of PMNs and prominent tissue necrosis, especially in the kidney [66,136,138]. Mycelia are frequently found invading the walls of blood vessels within infected tissues [15,67,136]. Retinal lesions, vitreal fungal lesions, and even lens abscesses with cataract formation have been described in neonates [139,140]. Evaluation of brain material shows significant inflammation with seeding of the meninges and may include parenchymal lesions, ventriculitis, perivasculitis, and ependymal inflammation [137,141–143]. Macroscopic fungus balls can form in fluid-filled spaces lined with epithelial or endothelial cells, such as the urinary tract, the central nervous system (CNS), and the intravascular space (particularly the right atrium) [117,144]. Fungus balls are large collections of intertwined hyphae, pseudohyphae, and yeast cells that presumably grow from *Candida* species initially adherent to the epithelial or endothelial surface of the involved organ [138,145,146]. Foreign bodies present in these fluid-filled spaces, such as urinary catheters, ventricular shunts, or central venous catheters, can also serve as the nidus for infection and precipitate the formation of a fungus ball [117,135,138,145,146].

In intrauterine candidal infections, macroscopic chorioamnionitis is evident, and histologic examination of the fetal membranes and the chorionic plate often reveal fungal elements with an extensive PMN infiltration [147,148]. Along with diffuse placental inflammation, focal granulomatous lesions can be present in the umbilical cord [140,149]. The detection of placental pathology consistent with candidal chorioamnionitis can lead to the early detection of congenital candidiasis in the infant [150].

## CLINICAL MANIFESTATIONS

*Candida* species are responsible for a variety of infections in neonates with a broad spectrum of clinical presentations, ranging from mild, irritating thrush and diaper dermatitis in the healthy term infant to life-threatening systemic disease in the extremely premature infant. The primary forms of candidiasis among infants are mucocutaneous infections, congenital candidiasis, catheter-related candidemia, and systemic or disseminated candidiasis. Individual organ system involvement (e.g., urinary tract infection, isolated meningitis, endophthalmitis) can occur, but infection occurs much more often as a component of disseminated infection, especially in the premature infant. Table 33–3 lists features of the various presentations of neonatal candidiasis.

### OROPHARYNGEAL CANDIDIASIS

Oropharyngeal candidiasis (i.e., thrush) can occur at any time during infancy. Among hospitalized infants, the overall incidence is reported as 3%, with a median age of onset of 9 to 10 days in NICU patients [151,152]. Specific risk factors include vaginal delivery, maternal vaginal *Candida* species infection, and birth asphyxia [152,153]. In a study of more than 500 mother-infant pairs, an eightfold increase was observed in the incidence of thrush among infants born to mothers with symptomatic candidal vaginitis compared with infants born to asymptomatic mothers [153]. A multivariate analysis of factors among NICU infants reported that birth asphyxia was the only event significantly associated with the development of thrush [152]. Although *Candida* species can be transmitted from mother to infant during breast-feeding, thrush occurs more often among formula-fed infants [154]. *C. albicans* is the most common species isolated from infants with thrush, but other NCAC species, such as *C. parapsilosis* and *C. glabrata*, increasingly are found as commensals and infecting agents [154–156].

Thrush manifests as irregular white plaques on the oral mucosa, including the buccal and lingual surfaces and the palate. The underlying mucosa may appear normal or erythematous and may have an ulcerative base to the white lesion. Physical removal of the plaques usually is difficult and often results in mucosal damage. Infected infants can be healthy or quite irritable, with disinterest in oral feedings and obvious discomfort with any care involving contact with the oral lesions.

### DIAPER DERMATITIS

Diaper dermatitis can occur any time during infancy, with a peak incidence at age 7 to 9 months in term infants (10% incidence) and approximately 10 to 11 weeks among VLBW infants (28% incidence) [46,157]. Most infants

**TABLE 33–3** Features of Neonatal Candidiasis

| Clinical Syndrome | Age at Onset | Host Risk Factors* | Presentation | Diagnosis | Treatment | Multiorgan Involvement | Prognosis |
|---|---|---|---|---|---|---|---|
| *Mucocutaneous Infections* | | | | | | | |
| Thrush | Throughout infancy | Birth asphyxia | White plaques on oral mucosa | Physical examination | Topical or oral antifungal therapy | None | Excellent |
| Diaper dermatitis | Throughout infancy; peak at 7–9 mo (term) and 10–11 wk (preterm) | Gastrointestinal colonization | Intense erythema of perineal area with satellite lesions | Physical examination | Topical antifungal therapy | None in term infants | Excellent |
| Congenital candidiasis | Birth | Premature rupture of membranes or uterine foreign body | Widespread erythematous maculopapular rash ± vesicles<br>Pneumonia in preterm infants | Physical examination<br>Culture of lesions for *Candida* spp | Topical antifungal therapy<br>Systemic antifungal therapy for pneumonia | Uncommon<br>Dissemination can occur in preterm infants | Excellent in term infants; excellent in preterm infants without dissemination |
| Invasive fungal dermatitis | <2 weeks | <1000 g<br>Vaginal delivery<br>Postnatal steroids<br>Hyperglycemia | Erosive, crusting lesions in dependent areas | Physical examination<br>Biopsy and culture of lesions | Systemic antifungal therapy | Common | Good if localized without dissemination |
| *Systemic Infections* | | | | | | | |
| Catheter-related infections | >7 days | Intravascular catheters | Sepsis | Blood culture by catheter grows *Candida* spp but peripheral blood cultures sterile | Catheter removal and systemic antifungal therapy | Rare Endocarditis or right atrial mass or thrombus | Good without dissemination or complication |
| Candidemia | >7 days | | Sepsis | Only blood cultures grow *Candida* spp | Systemic antifungal therapy | Common in VLBW infants | Good to fair<br>Risk of ROP in VLBW infants |
| Disseminated candidiasis | >7 days | | Severe sepsis<br>Multiorgan involvement | Blood and urine, CSF or other sites grow *Candida* spp<br>Clinical and/or radiographic evidence for multiorgan involvement | Systemic antifungal therapy | Always (sites most often involved are kidneys, CNS, eyes, heart) | Fair to poor |
| Renal candidiasis | >7 days | Congenital urinary tract anomalies<br>Neurogenic bladder | Sepsis<br>Urinary tract obstruction | Urine culture grows *Candida* spp<br>Ultrasound evidence of renal fungal lesions | Systemic antifungal therapy | Uncommon with isolated UTI | Good |
| CNS candidiasis | >7 days | Neural tube defects<br>Indwelling CSF shunt or catheter | Sepsis<br>None to focal neurologic signs | CSF culture grows *Candida* spp<br>CSF culture grows *Candida* spp ± signs of inflammation; lesions by cranial imaging | Systemic antifungal therapy | Common | Poor |

**Factors, in addition to those listed in Table 33–2, pertaining to the specific clinical syndrome listed.*
CNS, *central nervous system;* CSF, *cerebrospinal fluid;* ROP, *retinopathy of prematurity;* UTI, *urinary tract infection;* VLBW, *very low birth weight.*

with candidal diaper dermatitis have gastrointestinal colonization, with stool cultures positive for a *Candida* species [157]. Some infants also have oropharyngeal candidiasis. *C. albicans* is the most common species isolated, but there has been an increase in the recovery of other NCAC species, particularly *C. glabrata* and *C. parapsilosis*, when cultures are obtained [19].

The characteristic rash of candidal diaper dermatitis is confluent and intensely erythematous with satellite lesions and pustules [157,158]. As with oral thrush, the lesions can be very irritating to the infant, especially during normal perineal care. In the term infant, the rash resolves rapidly after treatment with an appropriate topical antifungal agent [154]. The preterm infant has a greater risk for spread beyond the diaper area. In a prospective study, Faix and colleagues found mucocutaneous disease in 7.8% of all preterm infants, and most had diaper dermatitis [151]. Among preterm infants with dermatitis and an associated change in clinical status, 32% developed systemic disease, compared with 2.1% of healthy infants [151]. Therefore, it is prudent to monitor the preterm infants with candidal diaper dermatitis for signs of systemic infection.

## CONGENITAL CANDIDIASIS

Congenital candidiasis typically presents at birth or within the first 24 hours of life, resulting from a maternal intrauterine infection or from massive exposure to maternal vaginal colonization with *Candida* during labor and delivery [19]. Hematogenous dissemination from mother to fetus, direct invasion of intact membranes, and ascending infection after ruptured membranes have been postulated as mechanisms for intrauterine infection [19,147,159]. Recognized risk factors for congenital candidiasis differ from those associated with postnatal infection and include prolonged rupture of membranes and the presence of an intrauterine foreign body, most commonly a cerclage suture [159,160]. Infants with the latter risk factor are more likely to be born prematurely and to have more severe skin involvement with disseminated disease [159]. While *C. albicans* is the predominant species responsible for congenital candidiasis, cases of congenital infections with *C. glabrata* and *C. parapsilosis* have been described [19,160,161].

Although there are rare case reports of infants with congenital candidiasis without skin involvement, the classic presentation is one of diffuse cutaneous disease [37,162,163]. Dermatologic findings include a widespread erythematous maculopapular rash, often with well-demarcated borders, that evolves into vesicles or pustules with eventual desquamation [160,162,163]. Any part of the skin may be involved, including the palms and soles, but the lesions typically are more prominent in the skin folds or intertriginous areas [19,164]. Preterm infants can have a diffuse, widespread, intensely erythematous dermatitis that resembles a mild burn or the early stages of staphylococcal scalded skin syndrome [165]. This form of congenital candidiasis often leads to massive desquamation, often accompanied by a prominent leukocytosis [37,162]. Extensive desquamation can lead to severe fluid and electrolyte imbalances in the extremely premature infant [37].

In term infants, clinical findings usually are limited to the skin, and recovery is uneventful after topical antifungal therapy. However, meningitis has been reported in the term infant with congenital candidiasis, and some infants may have nonspecific clinical signs of sepsis, such as poor perfusion, hypotonia, and temperature instability, suggesting systemic disease [162,166]. In preterm infants, cutaneous findings can be coupled with pulmonary invasion and early respiratory distress. In this circumstance, the chest radiograph is atypical for surfactant deficiency and the expected ground-glass appearance is replaced by a nodular or alveolar infiltrate [164]. Hematogenous dissemination is uncommon, but it can occur more frequently among preterm neonates and infants with widespread cutaneous involvement, pulmonary disease, and central intravascular catheters [160]. Every attempt should be made to avoid placing central intravascular catheters through the infected skin of patients with congenital candidiasis.

## INVASIVE FUNGAL DERMATITIS

Invasive fungal dermatitis is a unique clinical entity described in the ELBW infant occurring during the first 2 weeks of life [134,167]. *Candida* species are frequently isolated, but infection with other filamentous non-*Candida* fungi, including species of *Aspergillus*, *Trichosporon*, *Curvularia*, and *Bipolaris*, can result in this clinical presentation [134,168,169]. Specific risk factors for invasive fungal dermatitis include a gestational age less than 26 weeks, vaginal birth, postnatal steroid administration, and hyperglycemia [134]. The immature skin of the extremely preterm infant is not an efficient barrier to the external invasion of *Candida*, making these neonates more susceptible to invasive cutaneous disease. The stratum corneum of the preterm infant is extremely thin, and keratinization with maturation of the barrier properties typically occurs beyond the second week of life [160].

Neonates with invasive fungal dermatitis have characteristic skin lesions with severe erosions, serous drainage, and crusting, often occurring on dependent surfaces such as the back or abdomen [134]. Biopsy of the affected area shows invasion of fungal elements through the epidermis into the dermis [134]. Without prompt and appropriate therapy, dissemination with resulting widespread systemic disease is a frequent complication. As with congenital candidiasis, infants with extensive erosive lesions are at risk for the development of fluid and electrolyte abnormalities and secondary infections with other skin microorganisms.

## CATHETER-RELATED CANDIDAL INFECTIONS

Catheter-related candidal infections are disease processes of the sick, hospitalized preterm or term infant requiring prolonged use of intravascular catheters or other invasive means of support [40,48,122]. Almost any type of indwelling foreign body can become infected, but vascular catheter-related candidemia is the most frequent and serious infection. The incidence increases after a central vascular catheter has been in place for more than 7 days. These infections have been associated with umbilical

venous and arterial catheters and with percutaneously placed arterial or central venous catheters (i.e., femoral venous, subclavian, Broviac, or Silastic lines) [3,170]. Peripheral venous catheters have the same potential for fungemia in the premature infant, especially when used for the delivery of hyperalimentation fluid, and have been associated with the development of skin abscesses at the insertion site [171,172]. Catheter-related candida infection can occur in the absence of cutaneous infection in neonates with one or more of the predisposing conditions listed in Table 33–2, and the infection can arise from endogenous gastrointestinal organisms or from nosocomial transmission. Infected neonates exhibit nonspecific signs of sepsis, including feeding intolerance, apnea, hyperglycemia, and temperature instability, but no evidence of multiorgan involvement. Preterm infants also may exhibit hemodynamic instability or respiratory distress. Thrombocytopenia is a common presenting feature [4,173]. The vascular catheter tip provides an excellent nidus for growth of *Candida* and affords a source of ongoing fungemia. An infected thrombus or fungus ball can form on the catheter tip, serving as a source of platelet consumption or embolic dissemination [116,117]. By definition, catheter-related candidemia is infection of the catheter only; there is no dissemination or multiorgan involvement. Prompt catheter removal at the earliest sign of infection, although often impractical in the management of many of the highest-risk neonates, is necessary to contain the infection and prevent persistent candidemia with the attendant risk of developing disseminated infection or other complications. Candidal infections of right atrial catheters are associated with endocarditis and intracardiac fungal masses; the latter may result in cardiac dysfunction because of the enlarging right atrial mass [117,174].

Although infected intravascular catheters provide the greatest concern for dissemination, infection can occur with almost any type of catheter used in the treatment of the VLBW infant. Prolonged endotracheal intubation for mechanical ventilation can be required in the extremely premature infant with respiratory distress and in the sick term infant after cardiac or other extensive surgery. The concurrent ongoing presence of the endotracheal tube can lead to candidal colonization with the potential for development of pneumonia, although invasive lung infection is uncommon [25,95,175]. Candidal cystitis can accompany the prolonged use of indwelling bladder catheters by facilitating ascending infection, and cystic fungal masses can form, resulting in urethral obstruction [176–178]. Infants with vesicoureteral reflux and a candidal bladder infection are at increased risk for renal parenchymal infection [145,176]. Candidal peritonitis can develop with the prolonged use of peritoneal catheters placed intraoperatively for drainage or, more often, placed for peritoneal dialysis [135]. Peritoneal dialysis catheters are at extremely high risk for infection because of the frequent handling required and the high dextrose concentration of the indwelling dialysis fluid [135]. *Candida* species have been recovered from the pleural fluid draining from thoracic tubes and from the fluid draining through surgically placed mediastinal tubes [164]. With cystitis, dissemination and widespread disease can be complications, but *Candida* peritonitis or pleuritis rarely leads to fungemia [25,135].

## CANDIDEMIA AND DISSEMINATED CANDIDIASIS

Candidemia and disseminated or systemic candidiasis usually are associated with multiple invasive infection enhancing factors and are infections of the sick preterm or term infant who is in the NICU more than 7 days [122,136,179]. However, most cases occur among ELBW infants, who have an incidence of candidemia ranging from 5.5% to 20% [5,8,48]. The source of the infecting *Candida* species can be the infant's endogenous flora or from nosocomial transmission, and all the *Candida* species listed in Table 33–1 have been implicated in systemic disease [20,48,175]. While candidemia without organ involvement can occur, *Candida* spp. have such high affinity for certain organs (e.g., kidney, eye, heart, CNS) that dissemination appears to be the rule rather than the exception, particularly in the neonate with persistent fungemia [2,136,137]. The clinical presentation of the infant with candidemia can vary greatly depending upon the extent of systemic disease. The most common presentation is one with clinical features typical of bacterial sepsis, including lethargy, feeding intolerance, hyperbilirubinemia, apnea, cardiovascular instability, and the development or worsening of respiratory distress. The preterm infant can become critically ill, requiring a significant escalation in cardiorespiratory support. Fever rarely occurs, even with widespread disease. New-onset glucose intolerance and thrombocytopenia are common presenting findings that can persist until adequate therapy has been instituted and the infection contained [25,113,119,173]. This association is so strong that the presence of persistent hyperglycemia with thrombocytopenia in a neonate cared for in the NICU is almost diagnostic for untreated candidemia [173]. Leukocytosis with either a neutrophil predominance or neutropenia can be seen [102]. Neutropenia is more often associated with overwhelming systemic disease. Skin abscesses have been described with systemic disease and are attributed to the deposition of septic emboli in end vessels of the skin [180]. Infants also can have specific organ involvement, such as renal insufficiency, meningitis, endophthalmitis, endocarditis, or osteomyelitis, confirming dissemination. Complex multiorgan involvement is the hallmark of disseminated candidiasis, especially among VLBW premature infants, and results from diffuse hematogenous spread [8,181,182]. The suspicion or diagnosis of candidemia or the diagnosis of candidal infection of any single organ system should prompt a thorough examination and survey of the infant for additional organ involvement [2,182,183]. Almost any organ can become infected, but the most common sites for candidal dissemination are the urinary tract, the CNS, and the eye [2,137,181,182]. The specific clinical presentation for each of these systems is described separately in the following sections. For the infant with disseminated candidiasis, complications can be extensive, multiorgan system failure common, and the need for escalated intensive support frequent and prolonged [136,183].

### Renal Candidiasis

Renal involvement occurs in most infants with candidemia, because each of the same risk factors that predispose to disseminated disease specifically increase the risk for renal disease [184]. Every infant with candidemia should have an

evaluation of the urinary tract for candidal infection. Infants with congenital urinary tract anomalies and those requiring frequent catheterization for neurologic reasons are at increased risk for an isolated *Candida* species urinary tract infection (UTI) [144,145]. Congenital urinary tract anomalies, such as cloacal exstrophy, can provide a portal of entry for *Candida* species present on the skin. Urinary stasis, whether caused by a congenital anatomic obstruction or a functional obstruction (e.g., in the neurogenic bladder with myelomeningocele), increases the risk of candidal bladder infections [185]. Regardless of the underlying cause, candidal UTIs generally manifest with the same nonspecific systemic signs as with candidemia, whereas specific renal findings can be silent or manifest as urinary tract obstruction, hypertension, or renal failure [144,145,186–190]. Acute renal insufficiency or failure is a common clinical presentation and may be nonoliguric, oliguric, or anuric. In the nonoliguric form, urine output remains normal or near normal, but elevation of the serum creatinine level may be quite dramatic [144]. Renal ultrasonography often reveals parenchymal abnormalities suggestive of single or multiple abscesses; however, lesions may not be obvious at initial presentation, becoming evident only later in the disease process [145,186]. With oliguria, obstruction of the urinary tract by a discrete fungus ball or balls must be considered [187,188]. These fungal masses commonly are found in the ureteropelvic junction and usually are diagnosed by ultrasonography, but are found rarely by physical examination as a palpable flank mass [66,190]. Hypertension may be the only initial clinical feature in neonatal renal candidiasis [189].

## Central Nervous System Candidiasis

CNS candidiasis most often accompanies disseminated candidiasis, with up to 50% of VLBW infants having some form of CNS infection [191,192]. Neonates with neural tube defects and those requiring indwelling cerebrospinal fluid (CSF) shunts are at increased risk for isolated candidal infections of the CNS. Meningitis is the most frequently reported form of CNS infection, but parenchymal abscesses, ventriculitis, vasculitis and perivasculitis, ependymal inflammation, osteomyelitis of the skull or vertebral bodies, and even fungus balls within the subarachnoid space have been described, although rarely [2,137,146,193–196]. The specific clinical presentation is extremely variable but typically occurs when infants are older than 1 week [197,198]. The initial presentation is similar to that of disseminated candidiasis, subtle or quite severe, with cardiorespiratory instability and rapid overall deterioration [137]. Less frequently, an infant may have only neurologic signs, such as seizures, focal neurologic changes, an increase in head circumference, or a change in fontanelle quality [137,192]. Because clinical findings may be limited or nonexistent, the possibility of CNS involvement with *Candida* must always be considered in neonates with candidemia or evidence for invasive candidal disease at other sites.

## Candidal Ophthalmologic Infections

Endophthalmitis results from hematogenous spread of *Candida* species to the eye of the infant and is a diagnosed complication in approximately 6% of infants with systemic candidiasis [139]. Overall risk factors for ophthalmologic infection are the same as factors predisposing to disseminated disease. Infants with prolonged candidemia (i.e., blood cultures positive for more than 4 days) are significantly more likely to develop end-organ involvement of the eye, kidney, or heart [181]. Ophthalmic infections have been reported with all *Candida* species listed in Table 33–1 [181,199]. Because the clinical presentation of candidal chorioretinitis is frequently silent, an indirect ophthalmoscopic examination should be performed on all infants diagnosed with or suspected of having candidemia or systemic candidiasis. Lesions can be unilateral or bilateral, and these appear as individual yellow-white, elevated lesions with indistinct borders in the posterior fundus [139,199]. Vitreous lesions occasionally occur, and some infants show vitreal inflammation or a nonspecific choroidal lesion with hemorrhage or Roth spots in the posterior retina [141,182]. Infection of the lens occurs rarely; five case reports of lens abscesses in preterm infants exist, and each infant presented with a unilateral cataract [141,200–202].

In addition to the ophthalmologic infections caused by *Candida* species, an association between candidemia and retinopathy of prematurity (ROP) has been described in neonates with no previous evidence for chorioretinitis or endophthalmitis [203–209]. Early reports suggested a significant increase in the incidence of any stage ROP among infants with *Candida* sepsis compared with those without candidiasis (95% versus 69%) and an increased probability of severe ROP requiring laser surgery (41% versus 9%) [203]. Subsequent retrospective studies have demonstrated a greater incidence of threshold ROP and need for laser surgery among infants with *Candida* sepsis but no greater overall incidence of ROP of any severity [205,206,208–210]. Data are inconclusive as to cause and effect, but an association clearly is documented [140]. Premature infants of any gestational age who develop candidal sepsis should be followed closely by an ophthalmologist for the late development of severe ROP.

## Spontaneous Intestinal Perforation

Invasive disseminated candidiasis is associated with the occurrence of spontaneous intestinal perforation in preterm infants [135,211–214]. This syndrome is distinct from NEC, occurring predominantly during the first 2 to 3 weeks of life among the smallest, most premature infants on the NICU (median gestational age, 24 weeks; median birth weight, 634 g) [121]. Specific predisposing factors identified for spontaneous intestinal perforation include umbilical arterial catheterization, hypothermia, indomethacin therapy (prophylactic or treatment), and cyanotic congenital heart disease [135,214,215]. Neonates typically have bluish discoloration of the abdomen and a gasless pattern on abdominal radiographs, without pneumatosis intestinalis, often accompanied by systemic signs such as hypotension [121]. Disseminated candidiasis frequently is diagnosed in association with this syndrome; one series reported up to 33% of affected infants with cultures of blood, peritoneal fluid, CSF, or urine positive for *Candida* species [121]. Pathologic examination of the involved intestinal area demonstrates mucosal invasion by yeast and filamentous forms of *Candida* species

[126,211,214,215]. It is not clear from these specimens, nor from the clinical picture, whether the perforation is a result of primary candidal invasion of the intestinal mucosa or the colonizing *Candida* strain merely invades bowel damaged by another insult. Whatever the cause, the association exists; suggesting that clinicians should consider extensive evaluation for disseminated candidiasis with the diagnosis of a spontaneous intestinal perforation in the extremely premature infant.

## DIAGNOSIS

The diagnosis of most mucocutaneous disease is based on the characteristic clinical findings described earlier. Culture of the lesions of oral thrush or diaper dermatitis usually is not indicated. However, in an infant refractory to therapy, culture with susceptibility determination of the recovered organism may identify a NCAC species with a susceptibility pattern requiring modification of specific therapy [156]. In congenital candidiasis, a presumptive diagnosis can be made by Gram stain of vesicular contents of an individual lesion or by potassium hydroxide preparations of skin scrapings, with confirmation by culture of discrete lesions or swabs of skin folds or intertriginous areas. Cultures of blood, urine, and CSF are indicated for term infants with systemic signs of infection and for all affected preterm infants, healthy or ill appearing [37]. In the infant with change in respiratory or radiographic status, endotracheal aspirate cultures that grow *Candida* species are difficult to interpret because most often this represents colonization rather than pulmonary invasion [25]. The characteristic skin lesions of invasive fungal dermatitis often are diagnostic, but a skin biopsy provides a definitive diagnosis and tissue for culture and species determination. Biopsy is more sensitive than skin swabs in identifying other non-*Candida* filamentous fungi included in the differential diagnosis for this disease process [134].

Given the increasing incidence of invasive candidiasis among premature infants, clinicians caring for these infants must be alert to the possibility of *Candida* in any infant who develops signs of systemic infection, especially neonates with predisposing conditions (see Table 33–2). The differential diagnosis includes primarily other microorganisms responsible for nosocomial sepsis [175]. At a minimum, any infant with systemic signs of infection should have blood cultures obtained from a peripheral venipuncture and from all indwelling intravascular catheters. Most *Candida* species are identified by growth on standard bacteriologic culture media with aerobic processing, and requesting separate fungal cultures does not increase the yield of *Candida* species [8,64]. Previous recommendations were to monitor such cultures for up to 10 days to ensure adequate growth of the slower-growing *Candida* species [64,164]. However, in one report, 90% of cultures for *Candida* species were positive by 72 hours, before and immediately after the initiation of antifungal therapy [216]. Multiple or repeat blood cultures increase the likelihood of obtaining a positive result [217,218]. For infants with an indwelling intravascular catheter or catheters, samples obtained through each catheter and from a peripheral vessel are recommended for culture. Recovery of a *Candida* species from the culture sample obtained from an intravascular catheter and not from the peripheral blood supports the diagnosis of catheter-related candidemia without dissemination. However, caution should be used in making this distinction in neonates. First, the sensitivity of a single blood culture in diagnosing candidiasis is low; a single sterile peripheral blood culture does not exclude disseminated candidiasis [217]. Second, by the time the culture results are known (usually 24 to 48 hours after collection), dissemination might have occurred, especially in the preterm infant. Disparate results do indicate that the catheter tip is infected, and prompt removal of the catheter is indicated to prevent dissemination and other complications.

If disseminated candidiasis is suspected based on the clinical picture, or a positive blood culture is obtained from a peripheral vessel, additional studies are indicated. Even after the initiation of appropriate antifungal therapy, daily blood samples should be collected until culture results are negative, as the risk for multiorgan involvement increases the longer fungemia persists [181]. Because renal and CNS candidiasis can be clinically silent at presentation, urine and CSF should be obtained for analyses and culture. The presence of budding yeast or filamentous fungal forms by microscopic examination of the urine or CSF suggests invasive disease. Because *Candida* species are frequent contaminants of nonsterilely collected urine samples, urine should be obtained by sterile urethral catheterization or suprapubic aspiration [179,184]. In clinical practice, suprapubic aspiration is infrequently performed in many NICUs, and sterile urethral catheterization is reported to be an efficient method for obtaining urine cultures from infants younger than 6 months [219]. The current consensus is that a *Candida* species UTI in neonates be defined as $10^4$ or more colony-forming units of *Candida* species per mL in a culture obtained by sterile urethral catheterization [184,185]. Cultures of the CSF are more likely to be positive if the volume of CSF obtained is at least 1 mL [137]. Even when an optimal volume of CSF is cultured, a negative result does not eliminate the possibility of CNS disease because infection can occur in areas of the brain not in communication with the CSF [137,143,220]. Analysis of the CSF for abnormalities suggestive of inflammation, including an elevated white blood cell count or protein level or a decreased glucose level, suggests meningitis, but normal values do not exclude CNS infection [221]. Interpretation of CSF values can be complicated by the presence of blood due to a traumatic lumbar puncture or pre-existing intracranial hemorrhage in the preterm infant. Cultures of other clinically suspicious sites, such as peritoneal fluid or a skin abscess or vesicle, can help to confirm the diagnosis in an ill infant. However, cultures of healthy-appearing skin and mucous membranes or cultures of endotracheal secretions without the presence of pulmonary symptoms are not helpful in diagnosing systemic infections. Endotracheal tube secretion cultures may not be helpful in the infant with respiratory symptoms because *Candida* pneumonia is more often a result of hematogenous spread [46,179]. If any other catheters are present, such as chest or mediastinal tubes, cultures of the fluid drainage also should be obtained.

A culture from a usually sterile body site that grows *Candida* species confirms the diagnosis of candidiasis. Determination of the *Candida* species involved is equally important. Historically, because most infections were caused by *C. albicans*, many laboratories did not go beyond the initial identification of a yeast in culture as *Candida* [69,130,222]. Today, the incidence of infections with the NCAC species has increased dramatically, and identification of the species involved is important for epidemiologic and therapeutic reasons [164,223]. Knowledge of the infecting *Candida* species can help to determine whether the source of the infection is endogenous or from nosocomial transmission. This can be especially important in determining whether an apparent outbreak of candidiasis in a particular NICU is a coincidence or caused by a common source [50,54,55,222]. From the therapeutic perspective, when comparing the various pathogenic *Candida* species, variations exist in susceptibility to the common antifungal agents (Table 33–4), and defining the infecting *Candida* species is important in determining appropriate antifungal therapy [35].

To determine the extent and severity of candidiasis, additional laboratory tests are indicated when evaluating the infant with suspected disseminated candidiasis, including a complete blood count with differential and platelet counts and determinations of the levels of serum glucose, creatinine, blood urea nitrogen, bilirubin, liver transaminases, and C-reactive protein. The white blood cell count may be normal, high, or low; however, in the neonate, neutropenia may suggest a severe, overwhelming infection [127]. Thrombocytopenia is strongly associated with systemic candidiasis and may be an early indicator of this disease [161,173]. Elevations in the blood urea nitrogen and creatinine levels may indicate renal infection. Mild elevations in the serum bilirubin levels may be a part of the sepsis syndrome, but marked elevations in the serum bilirubin concentration or liver enzymes indicate extensive liver involvement [3]. Elevation of the C-reactive protein level is a nonspecific indicator of systemic infection [17,100]. Unfortunately, obtaining normal values for any or all of these ancillary laboratory tests does not completely exclude the possibility of candidiasis, especially CNS disease, in the high-risk neonate [137].

Because of the predilection of *Candida* for certain organs, specific imaging studies are indicated to diagnose the extent of dissemination. Renal ultrasonography, echocardiography, and cranial imaging are recommended for all infants with candidemia or systemic candidiasis [181]. Renal and bladder ultrasonography are extremely sensitive, but nonspecific, in their ability to define abnormalities resulting from *Candida* infections. The ultrasonographic appearance of a nonshadowing echogenic focus strongly suggests a renal fungus ball, particularly when the infant has a urine culture that grows *Candida* [224]. However, blood clots, fibrinous deposits, and nephrocalcinosis may have the same ultrasound appearance, confounding interpretation [225]. Another common ultrasonographic finding is renal parenchymal infiltration characterized by enlarged kidneys with diffusely increased echogenicity [224]. In any given infant with renal candidiasis, one or both of these ultrasound findings can be seen. Limited information exists about the accuracy of computed tomography (CT) or magnetic resonance imaging (MRI) in diagnosing renal candidiasis [226]. Echocardiography is useful in neonates with central venous catheters when the primary concern is for endocarditis with an infected thrombus at the catheter tip site or a right atrial mass [117,174]. Cranial ultrasonography easily can reveal enlarged ventricles, calcifications, cystic changes, and intraventricular fungus balls in infants with CNS candidiasis [142,186]. Ventriculitis can be diagnosed by the appearance of intraventricular septations or debris [137]. Interpretation of the cranial ultrasonography can be difficult in the preterm neonate who has experienced an intraventricular hemorrhage in the past or has developed periventricular leukomalacia. Intracranial abscesses due to *Candida* species reportedly have been mistaken for intracranial hemorrhage [227]. Cranial CT and MRI offer certain advantages over ultrasonography, including superior imaging of the posterior fossa and infratentorial and non-midline structures [228]. Calcifications are seen best with CT and the addition of intravenous contrast can aid in the identification of intracranial abscesses. However, as a practical matter, cranial ultrasonography is more frequently used because it can be performed at the bedside of a critically ill infant. In addition to these imaging studies, all neonates with confirmed or suspected candidemia should have a dilated ophthalmologic examination, preferably by a pediatric ophthalmologist

**TABLE 33–4** General Patterns of Susceptibility of *Candida* Species to Antifungal Agents

[139,199]. The infant who has characteristic lesions of *Candida* endophthalmitis has a confirmed diagnosis of disseminated disease.

Despite heightened awareness of the more subtle presentations of disseminated candidiasis and improvements in the ancillary and imaging studies available to clinicians, an accurate and timely diagnosis of candidal infections in the neonate remains a challenge. This largely reflects continued reliance on a positive culture for *Candida* species from a normally sterile body fluid (e.g., blood, urine, CSF, peritoneal fluid) or a potentially infected site to confirm the diagnosis and guide therapy. Autopsy studies suggest that the specificity of blood cultures for candidiasis approaches 100%; however, the sensitivity in the diagnosis of disseminated candidiasis is low, ranging from 30% with single organ involvement up to 80% with four or more organs involved [217]. The situation in the neonate is further complicated by the fact that fluid volumes as low as 1 mL may be obtained for culture, additionally diminishing the sensitivity especially if the total burden of organisms in the fluid is low [228]. The development of techniques for more sensitive, reliable, and rapid diagnosis of candidal infections is a priority and is an active area of investigation [229,230]. A number of molecular diagnostic assays that exploit recognition of small amounts of *Candida* species proteins or DNA, including the β-glucan antigen assay, scanning electron microscopy of fluid containing yeast, and polymerase chain reaction (PCR) testing, are being evaluated in adults and older children [230–232]. None of these assays has been rigorously evaluated in a population of neonates [183]. β-1,3-D-Glucan is a major component of the fungal cell wall found in all clinically relevant *Candida* species. Various assays are reported to have 85% sensitivity and 95% specificity for candidemia by detecting very small amounts of this fungal cell wall antigen [233,234]. PCR amplification of an area of the genome common to *C. albicans* and other pathogenic *Candida* species can be successfully performed, again using very small volumes of blood, urine, or CSF; this assay appears to be the best hope for rapid diagnosis [231]. Extensive use of PCR assays has previously been limited by unacceptably high rates of fungal contamination resulting in false-positive tests, but newer assays are more specific and sensitive [231,235–237]. Each of these assays holds promise for the rapid detection of fungus in small volumes of body fluids and does not require the presence of live *Candida* species. One major drawback to many early PCR assays, compared with culture, was the lack of differentiation between pathogenic *Candida* species; the diagnosis they provided was simply candidiasis. However, newer PCR assays are able to distinguish between various yeast species [235,237]. With specific culture or PCR results, the clinician knows which *Candida* species is causing the infection and can tailor the therapeutic plan accordingly. Without specific results, more generic management plans must be employed. However, because the institution of therapy often is delayed due to the lack of a positive culture when clinical deterioration begins, which may lead to systemic complications from persistent fungemia, knowing the neonate has a *Candida* species may lead to improved therapeutic management.

## TREATMENT

Therapy and management of candidiasis in the neonate require an effective antifungal agent coupled with appropriate supportive care and measures to eliminate factors favoring ongoing infection. In the NICU, the first two objectives are easier to achieve than the last. Multiple antifungal therapies are available, but few have been studied for determination of appropriate dose and interval, safety, and efficacy in neonates, especially VLBW infants. Amphotericin B has been the mainstay of antifungal therapy for more than 40 years, but newer agents may be indicated in certain settings [238–241]. Table 33–4 summarizes the antimicrobial susceptibility pattern of pathogenic *Candida* species to the most common antifungal agents, and Table 33–5 and the following discussion outline important features regarding use of each agent in the neonate with candidiasis. Because candidiasis often is a nosocomially acquired infection, most infected infants are already in the NICU, where appropriate intensive care to support these critically ill infants is readily available. If the hospital nursery is unable to address the needs of a critically ill neonate, transfer to a higher-level NICU should be considered. Unfortunately, the elimination of all risk factors for ongoing candidemia often is an unattainable goal, and the clinician frequently must settle for a less than optimal reduction of risk factors.

With the diagnosis of candidemia or disseminated candidiasis, immediate consideration should be given to the removal of all potentially contaminated medical hardware-especially central intravascular catheters [242]. For ongoing fungemia, successful medical treatment of *Candida* species infections while the catheters remain in place is rare [22,116,136]. The risk of dissemination also increases with every day the infant remains fungemic, as does the rate of infection of previously uninfected intravascular lines [136,243]. The clinician must face the reality that most preterm infants with systemic candidiasis require central access because of the clinical instability directly attributable to the ongoing candidemia, which in large part is caused by the ongoing presence of the infected catheter. If all lines cannot be removed, removal of a potentially infected catheter with insertion of a new line at a different site or a sequential reduction in the number of catheters is preferable to inaction. Infants with more than one catheter may not have all lines infected at the time of diagnosis, and removal of the catheter known or most likely to be infected may resolve the problem and allow continued therapy through the remaining line [118]. Antifungal therapy should be administered through the remaining central catheter to maximize drug delivery to a potential site of ongoing infection. Daily blood cultures to determine whether fungemia is persistent and whether additional infected catheters should be removed are necessary. Consideration should be given to surgical resection of infected tissue if antifungal therapy does not achieve sterilization (e.g., urine) or if mechanical complications caused by the presence of a fungus ball arise (e.g., right atrial mass). Although successful medical therapy for endocarditis caused by *Candida* species can often be achieved, large right atrial masses are almost impossible to sterilize and may also compromise hemodynamic function, necessitating surgical removal [117,118,174,227,244].

**TABLE 33–5** Systemic Antifungal Agents for the Treatment of Invasive Candidiasis in Neonates

| Drug | Dose | Interval | Route | Indications | Toxicities | Toxicity Monitoring | Comments |
|---|---|---|---|---|---|---|---|
| Amphotericin B | 0.5–1.0 mg/kg/day | q24h | IV | Candidemia, invasive candidiasis | Renal, hematologic, hepatic | Urine output, creatinine, potassium, magnesium, liver enzymes | Not indicated to treat C. lusitaniae Dose adjustments may be required for renal failure |
| Lipid-associated amphotericin B preparations | 3–5 mg/kg/day | q24h | IV | Invasive candidiasis with severe preexisting renal insufficiencies | Similar to amphotericin B | Urine output, creatinine, potassium, magnesium, liver enzymes | May be indicated in patients failing therapy or requiring higher doses |
| Flucytosine | 50–100 mg/kg/day | q12-24h | PO | For therapy in combination with amphotericin B with CNS infection | Renal, cardiac, hematologic, gastrointestinal, hepatic | Serum levels of liver enzymes, complete blood cell count with differential count | Desired serum levels 40–60 μg/mL; bone marrow toxicity can be severe; excellent CSF penetration |
| Fluconazole | 6–12 mg/kg/day | <7 d,[†] q72h<br>7–14 d, q48h<br>>14 d, q24h | PO, IV | Alternative therapy to amphotericin B for localized urinary tract infection, mucocutaneous disease | Hepatic, gastrointestinal | Liver enzymes | Excellent CSF penetration; oral formulation well absorbed; not indicated to treat C. krusei or C. Glabrata |
| Echinocandins* | | | | | | | |
| Caspofungin | 1–2 mg/kg/day | q24 hr | IV | Severe &/or refractory systemic infections hepatic & renal | Minimal, potential | Creatinine, urine output, liver enzymes | CSF penetration variable |
| Micafungin | 0.75–3 mg/kg/day | q24 hr | IV | Severe &/or refractory systemic infections hepatic & renal | Minimal, potential | Creatinine, urine output, liver enzymes | CSF penetration variable |

Surgical removal of an enlarging right atrial candidal mass in the face of ongoing fungemia and hemodynamic instability may be lifesaving for the premature infant [174]. Most renal fungal balls can be treated medically because of the high levels of most antifungal agents attained in the urine [176,185]. However, in an infant with complete obstruction of urinary flow caused by the presence of one or more fungal balls, surgical removal is indicated [187–189]. Hyperglycemia can be avoided by judicious administration of dextrose and insulin therapy if glucose intolerance persists. Corticosteroid therapy should be avoided or tapered as tolerated.

## ANTIFUNGAL AGENTS

### Topical Antifungal Therapy

Topical antifungal agents are indicated for thrush, diaper dermatitis, and uncomplicated congenital candidiasis in the term infant [19]. Nystatin, the most commonly used topical therapy, is a polyene drug that is not absorbed by the gastrointestinal tract, making it a topical agent in any of the three common formulations: oral suspension, ointment, or powder. The oral suspension is indicated for the treatment of thrush in patients of all ages. However, because of the high osmolality of the oral suspension (caused by the added sucrose expedient), care should be taken and use limited in the very premature infant or the neonate with compromise of the gastrointestinal tract [154]. Reports of clinical cure vary widely, from as low as 30% to as high as 85% [154,155]. Nystatin should be applied directly to the lesions of oral thrush. If swallowed rapidly, there is minimal contact with the lesions and little efficacy. Nystatin ointment or powder, when applied to diaper dermatitis, has an 85% cure rate [154]. Because thrush often accompanies diaper dermatitis, many clinicians add oral nystatin when prescribing perineal therapy, even if no oral lesions exist. Data suggest no added efficacy with this practice, which should be discouraged [154,245]. If oral lesions are present, treatment is indicated. However, if oral lesions are not present, the source of the *Candida* species probably is the lower gastrointestinal tract, in which nystatin is not an optimal agent.

Miconazole gel is a nonabsorbable formulation of this azole, developed particularly for treatment of thrush, which is not available in the United States [154,246]. The gel formulation is said to offer more prolonged contact with the oral lesions and has a reported efficacy of greater than 90% [154]. Side effects predominantly are gastrointestinal, similar to nystatin, but use of this agent has been evaluated only in a limited number of preterm infants [154]. Miconazole creams and ointments, and other topical azole formulations, frequently are prescribed for diaper dermatitis with excellent results [154,247].

Gentian violet, the first topical therapy for oral thrush, has become the treatment of last resort. Although effective, the liquid treatment must be applied directly to the lesions, and it causes unsightly dark purple stains on the infant's mouth, clothes, bedclothes, and often on the hands and clothes of the care provider. Complications include local irritation and ulceration from the direct application of the treatment to adjacent normal mucosa [154]. Given these inconveniences, most clinicians avoid gentian violet in favor of administering systemic therapy when topical treatments fail [155].

## Systemic Antifungal Therapy

### *Amphotericin B*

Amphotericin B deoxycholate is a polyene antifungal agent available since the 1960s. The American Academy of Pediatrics Committee on Infectious Diseases, the Pediatric Infectious Disease Society (PIDS), and the Infectious Disease Society of America (IDSA) recommend amphotericin B as the primary antifungal agent for the treatment of candidemia, disseminated candidiasis, and any form of invasive candidiasis in the neonate [248–251]. Most pathogenic *Candida* species are susceptible to amphotericin B (see Table 33–4). However, reports suggest a proportion of *C. glabrata* and *C. krusei* isolates have a somewhat reduced susceptibility to amphotericin B, which can be overcome by using higher dose therapy, and resistance has been described for isolates of *C. lusitaniae*.* Very occasional resistance with *C. parapsilosis* has been reported [254].

Amphotericin B acts by binding to ergosterol in the fungal cell membrane, altering cell permeability with subsequent depolarization and leakage of cytoplasmic contents, eventually leading to cell death. Although amphotericin B has a higher affinity for ergosterol than the cholesterol in human cell membranes, toxicity is a risk with this drug. Neonates tolerate the drug well with minimal toxicity [255,256]. Toxicities reported in neonates receiving amphotericin B include renal insufficiency with occasional renal failure, hypokalemia, and hypomagnesemia caused by excessive renal losses, bone marrow suppression with anemia and thrombocytopenia, and abnormalities in hepatic enzymes [221,257]. Most toxicities are dose dependent and reversible on cessation of therapy [257]. Nephrotoxicity is the most common and worrisome toxic effect. A substantial rise in creatinine and decrease in urine output can be observed; however, it is frequently difficult to differentiate between renal insufficiency caused by inadequately treated systemic renal candidiasis and that due to amphotericin B. Amphotericin B-induced nephrogenic diabetes insipidus has been described in adults, but not in neonates [258]. Although there is a potential for renal failure, most infants display no or mild nephrotoxicity that resolves with decreasing the dose of amphotericin B or after completion of therapy. A common and very uncomfortable side effect in adults and older children receiving amphotericin B is an infusion-related reaction consisting of fever, chills, nausea, headache, and occasional hypotension [256]. No such toxicity has been described in neonates [238,255,256]. Any neonate receiving amphotericin B should have serial monitoring of serum potassium and magnesium levels and of renal, liver, and bone marrow function.

Amphotericin B is not water soluble and is available only as an intravenous preparation. In neonates, there is a tremendous variability in the half-life, clearance, and peak serum concentrations after dosing [238,255,256]. Treatment success in neonates has been documented at doses of 0.5 to 1.5 mg/kg/day [193,255,259,260]. Most clinicians initiate therapy with a dose of 0.5 mg/kg and increase it to 1.0 mg/kg given once daily if no significant toxicity occurs. Dosing may need to be adjusted in the infant with pre-existing renal insufficiency [248]. Doses greater than 1.0 mg/kg daily rarely are needed for treating *Candida* species infections. The test dose, historically given to adults to determine the need for medication to ameliorate infusion-related symptoms, is not required in neonates. The risk for dissemination is so high among infants that no delay should occur in delivering treatment doses.

Although excellent plasma levels and tissue penetration occur with this dosing regimen for amphotericin B, CSF penetration is variable. In adults, CSF concentrations of amphotericin B are only 5% to 10% of plasma levels [248]. Neonatal CSF concentrations of amphotericin B generally are higher but more variable, ranging from 40% to 90% of plasma levels in one study of preterm infants [261]. The higher CSF concentrations achieved in neonates compared with adults may be related to the immature blood-brain barrier. However, the variability in concentrations suggests to some clinicians that amphotericin B as a single agent for the treatment of neonatal CNS infections may be ineffective. Fluconazole and 5-flucytosine penetrate the CSF well and can provide synergy with amphotericin B in killing some *Candida* species, especially *C. albicans*. Combinations of one or both of these agents with amphotericin B have resulted in successful treatment of CNS candidiasis in infants where single therapy alone was unsuccessful [193,262,263]. Successful treatment of CNS disease with amphotericin monotherapy also has been reported [221,255,259]. Systemic amphotericin may not be necessary in the few infants with isolated bladder candidal infection. In rare cases, bladder instillation of amphotericin B, alone or in combination with fluconazole, has been successfully used to treat infants with isolated cystitis or urinary tract fungal balls [185,264].

### *Amphotericin B Lipid Formulations*

As an alternative to standard amphotericin B, three lipid-associated formulations are approved for use in adults: liposomal amphotericin B (L-AmB), amphotericin B lipid

*References 12, 131, 241, 248, 252, 253.

complex (ABLC), and amphotericin B cholesterol sulfate complex (ABCD). Fungal susceptibility patterns for these lipid-associated formulations are the same as for conventional amphotericin B deoxycholate [265–267]. Each is significantly more expensive than conventional amphotericin B [239]. The main purported advantage to these amphotericin B preparations is the ability to deliver a higher dose of medication with lower levels of toxicity. In adults and older children receiving a lipid-formulation of amphotericin B, significantly lower rates of infusion-related reactions and creatinine elevations are reported compared with conventional amphotericin B [268]. Several case reports of successful use of these preparations in neonates have been published, but almost no controlled studies have been performed [266,267,269,270]. Three studies of liposomal amphotericin B that have included neonates demonstrated no major adverse events, diminished toxicities associated with conventional amphotericin (i.e., hypokalemia and hyperbilirubinemia), and treatment success rates of 70% to 100% [265,271,272]. Two studies of ABLC in pediatric patients have included small numbers of neonates and demonstrated efficacy rates of 75% to 85%, with no significant toxicities [266,267]. CNS penetration may be better with these preparations in adult patients, but there are no data for neonates to support this claim [267]. Renal penetration of the lipid-associated formulations is poor compared with conventional amphotericin, and treatment failure at this site of infection has been reported [177,263,268].

Although randomized, controlled trials of the lipid-associated preparations in neonates are lacking, available information suggests that they may be safe and effective, although not superior to conventional amphotericin B. Treatment with amphotericin B deoxycholate remains the most appropriate therapy for infants with invasive infections with *Candida* species, especially for those with renal infection [239,248,249]. The amphotericin B lipid formulations may have a role in the treatment of invasive candidiasis in neonates with pre-existing severe renal disease or infants who fail to respond to conventional amphotericin B after removal of all intravascular catheters, but more data are needed.

## Fluorocytosine

5-Flucytosine (5-FC) is a fluorine analogue of cytosine. The antifungal activity of 5-FC is based on its conversion to 5-fluorouracil, which inhibits thymidylate synthetase, disrupting DNA synthesis. This mechanism of action is not fungal specific, and significant host toxicities are reported in adults [239]. All pathogenic *Candida* species are susceptible to this agent, but resistance develops rapidly when used as monotherapy (see Table 33–4) [252]. 5-FC has excellent CNS penetration and is used primarily in combination with amphotericin B in the treatment of neonatal CNS candidiasis because early studies demonstrated synergy with these two agents [193,252,262]. However, other reports suggest no added therapeutic benefit when 5-FC is combined with amphotericin B [239,255,273]. The potential benefit of 5-FC added to amphotericin B must be weighed against potentially significant toxicities when considering the use of this agent. Flucytosine is available only in an enteral preparation, limiting its use in most critically ill neonates with systemic candidiasis.

## Azoles

The azoles are a class of synthetic fungistatic agents that inhibit fungal growth through inhibition of the fungal cytochrome P-450 system [274]. This action is not fungal specific, and interactions with the host cytochrome P-450 system can cause alterations in the pharmacokinetics of concomitant medications the infant is receiving and produce hepatotoxicity. Clinical hepatotoxicity is rare with use of the newer azoles, such as fluconazole and voriconazole, in adults and older children, and their overall safety profile is favorable [275]. However, monitoring of transaminases in patients receiving azoles is recommended [238]. Adverse endocrine and metabolic effects have been attributed to the use of azoles in adults [276]. The development of fungal resistance is a significant concern with this class of antifungal agents (see Table 33–4) [12].

Fluconazole, the azole used most frequently in neonates, is water soluble, available in oral or intravenous preparations, and highly bioavailable in the neonate [238,277]. Fluconazole has a long plasma half-life, with excellent levels achieved in the blood, CSF, brain, liver, spleen, and especially the kidneys, where it is excreted unchanged in the urine [278]. The pharmacokinetics of fluconazole in neonates change dramatically over the first weeks of life, presumably because of increased renal clearance with maturity; therefore, the dosing interval is based on both postnatal and postconceptual age (see Table 33–5) [278,279]. Transient thrombocytopenia, elevations in creatinine, mild hyperbilirubinemia, and transient increases in liver transaminases have been documented in neonates [31,278,280].

Several studies have shown fluconazole to be efficacious in the treatment of invasive candidiasis in the neonate. In one prospective, randomized trial versus amphotericin B, rates of survival and clearance of the organism were equivalent for both treatment groups [281–283]. Infants treated with fluconazole had less renal and hepatic toxicity and had a shorter time to the complete removal of central intravascular catheters, which was attributed to the ability to convert to oral therapy for completion of the treatment course [281]. Although these features make the use of fluconazole appear quite attractive, the primary concern with fluconazole is the potential for fungi to develop resistance [15,252]. Although most pathogenic *Candida* species are susceptible to fluconazole, *C. krusei* is intrinsically resistant to this azole, as are up to 65% of *C. glabrata* isolates (see Table 33–4) [131,240,284,285]. Both of these NCAC species can cause neonatal disease; therefore, the use of fluconazole as empirical single therapy is not recommended. The IDSA guidelines recommend the administration of fluconazole as an alternative therapy to amphotericin B for disseminated, invasive neonatal candidiasis or congenital candidiasis with systemic signs after the pathogenic *Candida* species is identified and susceptibility determination completed [248]. Because of its unaltered renal clearance, fluconazole is an excellent choice for the treatment of isolated urinary tract infections resulting from susceptible

*Candida* species, and oral fluconazole is an alternative therapy in refractory mucocutaneous disease [155,277,279]. Combination therapy with amphotericin B was evaluated in a multicellular trial of nonneutropenic adults with candidemia with excellent results [243]. Due to the excellent CSF preparation of fluconazole, combination therapy with amphotericin has been suggested when CNS disease is present [137].

Voriconazole is a second-generation azole, derived from fluconazole, with increased potency and a broader spectrum of activity (see Table 33–4) [286–288]. Voriconazole is active in vitro against all clinically relevant *Candida* species, including *C. krusei* and *C. glabrata*, and no resistance by fluconazole-resistant strains has been seen [12,289]. Voriconazole is metabolized by the liver, and the only clinically significant adverse event reported in adults is the occurrence of visual disturbances [286]. For this reason concerns have been raised about the possibility of unknown interactions with the developing retina, discouraging therapeutic trials in neonates [250]. The neonatal literature is limited, but one case report does describe successful combination therapy with voriconazole and liposomal amphotericin B in a premature infant with disseminated fluconazole resistant *C. albicans* infection [290]. A more recent report showed safety and efficacy in a very small group of neonates treated with voriconazole [291]. Although this agent appears to be safe and effective in children, further trials in neonates are indicated before routine recommendation can be established. Posaconazole and ravuconazole are the two newest triazoles and there is no data available on their use in either pediatric or neonatal patients.

### *Echinocandins*

Echinocandins are a novel class of antifungal drugs that act by a unique and completely fungal-specific mechanism—inhibition of the synthesis of β-1,3-D-glucan, an essential component of the fungal cell wall [292]. Because there is no mammalian equivalent to the fungal cell wall, the safety profile for the echinocandins is excellent and significantly better than the polyenes or azoles [240,292]. Three drugs in this class, anidulafungin, caspofungin, and micafungin, are currently only licensed for use in the United States as intravenous formulations because of poor oral availability [250]. Echinocandins are fungicidal against all pathogenic *Candida* species [241,293]. Concerns have been raised that *C. parapsilosis* may be less susceptible to this drug based on in vitro testing, but clinical response to invasive disease in adults has been excellent [294]. Because the mechanism of action is completely different from the other antifungal agents currently in use, the echinocandins are excellent candidates for use in combined therapy, especially for refractory infections. Pharmacokinetic studies in the neonatal population are limited, but those completed show caspofungin and micafungin are well tolerated, but have a shorter serum half-life and more rapid clearance, emphasizing the importance of evaluating the neonatal population separate from older children and adults [250,295]. Recommendations for optimal dosage in the neonate, especially preterm, for either of these agents remain unclear [250]. Multiple case reports suggest safety and efficacy [296–300]. One multicenter trial of micafungin in pediatric, adult, and neonatal patients demonstrated an overall greater than 80% success rate in treating refractory candidemia, either alone or in combination with other antifungal agents, but the number of neonates enrolled was small [301]. A review of the use of caspofungin in pediatric patients was also favorable, as was a recent pharmacokinetic study among infants less than 3 months of age [300,302]. No data has been published regarding the use of anidulafungin in neonates. The most current guidelines from the IDSA recommend caspofungin as a second-line agent for neonatal candidemia without dissemination [248]. Development of this novel class of truly fungicidal agents against *Candida* spp. has greatly expanded our options for treating invasive candidiasis in adults. If the echinocandins prove to be as safe and effective for neonates, clinicians could have the ability to combine antifungal agents with different general mechanisms of action (i.e., amphotericin B + an echinocandin, or an azole + an echinocandin) to optimize therapeutic efficacy.

## Length of Therapy

No matter which antifungal therapy is chosen, the length of therapy to adequately treat invasive neonatal candidiasis is prolonged (see Table 33–3). There are no controlled clinical trials to provide the optimal length of therapy for any of the antifungal agents and no consensus among neonatologists and pediatric infectious disease specialists [263]. The IDSA recommends a minimum of 14 to 21 days of systemic therapy after negative blood, urine, and CSF culture results have been obtained along with the resolution of clinical findings [248]. Case series employing amphotericin B suggest that a cumulative dose of 25 to 30 mg/kg be administered (estimated at a mean of 4 weeks) [3,255]. Therapy for endocarditis typically lasts 6 weeks [248]. In neonates with isolated *Candida* cystitis, treatment for 7 days appears to be adequate. Therapy must be administered intravenous initially, but in an infant who responds to fluconazole, completion of the course with oral therapy is acceptable [279]. Infants with fungal abscesses, renal lesions, intracranial lesions, or right atrial fungal masses should have sonographic or radiographic evidence of resolution before completing therapy [144,224,238]. Close monitoring for relapse after the cessation of therapy is necessary given the high rate of recurrence, especially in infants with CNS disease [2,137,200].

## Prognosis

Despite the current advances in neonatal care and antifungal therapy, the prognosis for the infant who develops an invasive fungal infection is still quite variable, but generally poor. Mortality rates range from 20% to 50%, with significant accompanying morbidity [151,170,303]. Factors determining the final prognosis include the degree of prematurity, extent of dissemination, severity of illness, and the rapidity of institution of appropriate antifungal and supportive therapy [304]. Infants with isolated catheter-related candidal infections, uncomplicated urinary tract infections, or candidemia without dissemination tend to have a good outcome with the potential for

complete recovery without sequelae. Infants with extreme prematurity, widely disseminated disease, multiorgan involvement, renal or hepatic failure, and ophthalmologic or CNS infection have a much worse prognosis. In studies of VLBW infants surviving candidemia, disseminated candidiasis, or candidal meningitis, candidiasis survivors were significantly more likely to have a major neurologic abnormality (40% to 60% versus 11% to 25%) and a subnormal (<70) Mental Developmental Index (40% versus 14%) than noninfected infants of the same gestational age and birth weight [141,170]. In a series of ELBW neonates with disseminated candidiasis, including meningitis, Friedman and colleagues found a higher incidence of chronic lung disease (100% versus 33%), periventricular leukomalacia (26% versus 12%), severe ROP (22% versus 9%), and adverse neurologic outcomes at 2 years' corrected age (60% versus 35%) for infected infants than for gestational age- and birth weight-matched, noninfected controls [304]. Among the infected neonates with adverse neurologic outcomes, 41% had severe disabilities compared with 12% of the control infants, and all infants with parenchymal brain lesions diagnosed by cranial ultrasonography at the time of candidiasis had poor neurologic outcomes [22]. The visual outcome following endophthalmitis is generally good after provision of appropriate systemic antifungal therapy. Only a small percentage of infants have significant visual impairment, although most have some decrease in visual acuity [139]. Severe ROP has developed in preterm infants who recovered from candidiasis but never had endophthalmitis [204,207]. These infants may require laser surgery and may be at significant risk for vision loss [204]. Great strides have been made in our ability to diagnose and treat invasive candidiasis, but we must strive to continue to improve therapeutic management and address the issues of morbidity.

## PREVENTION

The old adage that "an ounce of prevention is worth a pound of cure" could never be truer than when considering neonatal candidiasis. Treatment is difficult, prolonged, and prevents mortality and morbidity little more than one half of the time. The development of strategies to prevent neonatal candidal infections should be a priority on the NICU. Many of the factors listed in Table 33–2 that enhance the risk for candidiasis are unavoidable, such as prematurity and low birth weight, but every attempt should be made to address conditions that can be reduced, starting with exposure to the yeast itself. Appropriate diagnosis and treatment of maternal candidal vaginosis and urinary tract infections during pregnancy may decrease vertical transmission [248]. Prevention of horizontal transmission from caregivers by the use of good hand hygiene and gloves has resulted in limited success [49,50,305]. In studies of health care workers, appropriate hand hygiene is helpful in reducing superficial and transient flora, but it does not affect deep and permanent flora overall, with no significant reduction in the recovery of *C. albicans* detected after antimicrobial or alcohol washes [53,306–309]. Elimination of artificial fingernails among care providers and the judicious use of gloves may reduce exposure and transmission [50]. The meticulous care of long-term indwelling catheters is recommended, especially if used to administer hyperalimentation.

Reduction in exposures to medications associated with neonatal candidiasis is an important part of prevention. Broad-spectrum antibiotic therapy and the postnatal use of hydrocortisone and dexamethasone are associated with fungal sepsis [48,111,203,305]. Two separate multicenter trials have shown an association between heavy levels of gastrointestinal tract colonization with *Candida* species and exposure to third-generation cephalosporins or H2 antagonists [48,305]. Both medications alter the enteric microenvironment, favoring fungal colonization and potential dissemination. The use of topical petrolatum ointment in skin care of the ELBW infant is associated with a significantly increased incidence of invasive candidal infections [310]. Although attempts at providing good skin care to prevent epidermal breakdown in the ELBW infant are laudable, the use of petrolatum ointment does not appear to be the best choice, and the increased risk of infection appears to outweigh any potential benefits.

## FLUCONAZOLE PROPHYLAXIS

Chemoprophylaxis with antifungal agents such as oral nystatin and especially fluconazole has been a major area for investigation in recent years, with the goal of reducing candidal colonization and the accompanying potential for invasive disseminated disease. The cardinal rule of antimicrobial prophylaxis is to use one agent with minimal toxicities for prophylaxis and others for therapy. The use of oral nystatin to prevent systemic candidiasis has been practiced in many NICUs for decades, is tolerated well by neonates, with no fungal resistance documented, but efficacy in preventing invasive infection is not consistently achieved [171,311–313]. The development of multiple new antifungal agents (as described in the preceding section on treatment) has lead to the selection of fluconazole as the best new agent for anticandidal prophylaxis in the neonate [314,315]. Meta-analysis of four published randomized controlled trials of systemic antifungal prophylaxis with fluconazole in VLBW infants showed a significantly lower incidence of invasive fungal infection in the fluconazole group (RR 0.23), reduced mortality (RR 0.61), and an estimated number needed to treat (NNT) to prevent one extra case of invasive fungal infection of 130 in the overall VLBW population or 62 for ELBW infants [23,31,315–317]. All studies demonstrated safety, with no emergence of fungal resistance [314]. However, when looked at individually, the significance of the reduction in infection is dependent upon the baseline rate of systemic candidiasis in the participating nurseries. The most impressive reduction, NNT of 5, was reported in the study with the highest incidence of disease in the placebo group [31]. Institutional variability exists with respect to overall rates of infection, and discrepancies within subpopulations—such as ELBW infants, or those with multiple risk factors as listed in Table 33–2. These observations indicate that the NNT may vary dramatically based on the baseline incidence of systemic candidiasis for an individual NICU, suggesting that the basis for recommendations regarding fluconazole prophylaxis should be specific

NICU characteristics, rather than be universal guidelines [318]. Alternatively, targeted prophylaxis for the highest risk patents may be the best approach. Subsequent studies evaluating this approach for the preterm infant less than 1000 g or less than 27 weeks or those with specific accompanying risk factors (central venous catheter or >3 days of antibiotics) over a more limited period of time have shown a reduction in both invasive disease and mortality [314]. The targeted prophylaxis approach also limits drug exposure, reducing concerns for the emergence of drug resistance [35,289,319]. Widespread fluconazole prophylaxis in adult patients has clearly been associated with the development of resistant microorganisms and it would be naïve to ignore this concern in the nursery [320]. While the majority of published studies do not report the emergence of resistant *Candida*, follow-up to date is short term and fluconazole-resistant *C. parapsilosis* isolates colonizing neonates were reported by one group after the institution of a fluconazole prophylaxis program for ELBW infants [280,321]. The role for fluconazole prophylaxis, targeted or not, requires further clarification. Additional studies are indicated to explore the use of novel therapies for the prevention of *Candida* species colonization and systemic disease.

CHAPTER

# 34 *PNEUMOCYSTIS* AND OTHER LESS COMMON FUNGAL INFECTIONS

**Yvonne A. Maldonado**

## CHAPTER OUTLINE

Fungal infections, other than those caused by *Candida* species, rarely are considered in the differential diagnosis for an acutely ill newborn infant because disorders of bacterial and viral etiology are vastly more common. Nevertheless, fungal infections do occur in neonates, especially in premature infants and those of very low birth weight (less than 1500 g), and can cause serious and frequently fatal disease. The number of cases of invasive infection attributed to fungi among all patients in the United States quadrupled between 1990 and 2000. With advances in neonatal care, the epidemiology of fungal infections in the neonatal intensive care unit (NICU) has changed

DOI: 10.1016/B978-1-4160-6400-8.00034-1

dramatically, with an estimated tenfold increase in the past decade. As with any other infectious disease, the risk of fungal infection depends on the host and risk of exposure. The neonate has some risk of exposure to either *Malassezia furfur* or *Pneumocystis jiroveci* (previously *Pneumocystis carinii*, classified as a fungus on the basis of DNA sequence analysis), has a limited risk of exposure to *Aspergillus* species, and has an extremely low risk of exposure to other fungi—especially in the NICU setting. Therefore, it is not surprising that the most common fungal infection in neonates is candidiasis, followed by infections with *P. jiroveci* and *M. furfur*, whereas case reports or small series constitute the literature on aspergillosis and other fungal infections.

Mycotic infections, whether confined to epidermal structures or involving deep tissues, are caused by fungi free-living in soil or present in bird or mammal excreta or in decaying organic matter. In instances of fungal infection in newborns, organisms most often are acquired in utero through the hematogenous route, from the mother during birth, or from the environment on postnatal exposure. When inhaled, ingested, or inoculated directly into tissue, these saprophytic micro-organisms can cause infection after birth in infants with undue susceptibility. Although much has been learned regarding the pathogenesis, immune response, and treatment of fungal infections in older children and adults, studies to determine the cause of increased susceptibility or resistance to infection with fungi, especially in neonates, are incomplete. Limited published studies that prophylactic antifungal therapy of hospitalized high risk neonates, primarily with fluconazole, may decrease the rate of systemic fungal infections. In these studies the primary outcome has generally been the prevention of systemic candidiasis [1]. Advances have been made in the diagnosis and treatment of neonatal fungal infections, however.

## *PNEUMOCYSTIS JIROVECI* (FORMERLY KNOWN AS *PNEUMOCYSTIS CARINII*) INFECTION

*P. jiroveci*, a fungus with a history of unsettled taxonomy, was discovered in the lungs of small mammals and humans in Brazil more than 80 years ago. Today it is a cause of often fatal pneumonia in patients with immunodeficiencies, hematologic malignancy, collagen-vascular disorders, or organ allografts and in those who receive corticosteroids and immunosuppressive drug therapy. Although congenital or neonatal infection with *Pneumocystis* is uncommon, it can occur in infants younger than 1 year of age in two well-defined epidemiologic settings: (1) in epidemics in nurseries located in impoverished areas of the world and (2) in isolated cases in which the infected child has an underlying primary immunodeficiency disease [2] or acquired immunodeficiency syndrome (AIDS).

This section of the chapter reviews the problem of *Pneumocystis* infection in the newborn. Much of our knowledge of the epidemiologic, pathologic, and clinical features of pneumocystosis, however, is drawn from observations of the infection in older children and adults. As a result, we have elected to include data derived from such observations to present a more complete picture of the infectious process caused by this unique organism.

### HISTORY

In 1909, Chagas [3] in Brazil first described the morphologic forms of *Pneumocystis* in the lungs of guinea pigs infected with *Trypanosoma cruzi*. He believed the forms to represent a sexual stage in the life cycle of the trypanosome and not a different organism. Carini [4], an Italian working in Brazil, saw the same organism-like cysts in the lungs of rats experimentally infected with *Trypanosoma lewisi*. His slide material subsequently was reviewed by the Delanoës and their colleagues [5] at the Pasteur Institute in Paris. They recognized that these alveolar cysts were present in the lungs of local Parisian sewer rats and thereby established that the "organisms" were independent of trypanosomes. They proposed the name *P. carinii* for the new species.

At about this time, Chagas may have unwittingly described the first human case of pneumocystosis when he reported the presence of similar organisms in the lungs of a patient with interstitial pneumonia who had died of American trypanosomiasis [6]. Nevertheless, no definite etiologic connection was made between *P. carinii* and human pneumonic disease for another 30 years. The reason for this delay was the belief during this period that infantile syphilis was responsible for virtually all instances of interstitial plasma cell pneumonia. In 1938, Benecke [7] and Ammich [8] identified a histologically similar pneumonic illness in nonsyphilitic children that was characterized by a peculiar honeycombed exudate in alveoli. Subsequent scrutiny of photomicrographs in their reports revealed the presence of *P. carinii* organisms [9], but it was not until 1942 that Van der Meer and Brug [10] in the Netherlands unequivocally recognized the organism in lungs from two infants and one adult. The first epidemics of interstitial plasma cell pneumonia were reported shortly thereafter among premature debilitated babies in nurseries and foundling homes in central Europe. In 1952 Vanek and Jirovec [9] in Czechoslovakia provided the most convincing demonstration of the etiologic relationship of *P. carinii* to this disease in an autopsy study of 16 cases.

Pneumocystosis was first brought to the attention of pediatricians in the United States in 1953 by Deamer and Zollinger [11], who reviewed the pathologic and epidemiologic features of the European disease. Lunseth and associates [12] generally are credited for the initial case report of interstitial plasma cell pneumonia occurring in an infant born in the United States. Curiously, the latter authors neither identified *Pneumocystis* organisms in their histologic sections nor even alluded to the organism in their discussion of causation of the disease. During the next year, the presence of *Pneumocystis* pneumonia in the United States was documented in several published studies [13–15].

In 1957 Gajdusek [16] presented an in-depth perspective on the history of the infection that included an extensive bibliography. This review was particularly timely because the next decade was to see the disturbing

emergence of *P. carinii* pneumonia in the Western world—even while the epidemic disease in central Europe was waning—to the degree that it would become pre-eminent among the so-called opportunistic pulmonary infections in the immunosuppressed host. In 1988, DNA analysis demonstrated that *Pneumocystis* was not a protozoan but a fungus [17,18]. Subsequent DNA analysis has led to the change in nomenclature from *P. carinii* to *P. jiroveci*, a name chosen in honor of the parasitologist Otto Jirovec, who now is credited by some with the original description of this organism [19,20].

## THE ORGANISM

The precise taxonomic status of *P. jiroveci* as a fungus has been defined on the basis of molecular analysis [17,18]. Because the organism has only recently been propagated in vitro, efforts to classify it and to elucidate its structure and life cycle have been based exclusively on morphologic observations of infected lungs from animals and humans. The earliest of these investigations was performed by parasitologists; accordingly, the terminology applied to the forms of *Pneumocystis* seen in diseased tissue has been that reserved for protozoal organisms.

Three developmental forms of this presumably unicellular microbe [21] have been described: a thick-walled cyst, an intracystic sporozoite, and a thin-walled trophozoite [4,22,23]. The form of *Pneumocystis* that assists with diagnosis is the cyst, which may contain up to eight sporozoites. Each sporozoite is round to crescent shaped, measures 1 to 2 μm in diameter, and contains an eccentric nucleus. This cystic unit with its intracystic bodies is seen well in Giemsa-stained imprint smears of infected fresh lung [16,24]. Giemsa stain, however, results in staining of background alveoli and host cell fragments and does not stain empty cysts. Gomori methenamine silver stain, which highlights only the cyst wall of *Pneumocystis*, is preferable to Giemsa stain when tissues must be screened for the presence of organisms [25–27]. The cysts stained with silver have a thin, often wrinkled black capsule that may be round, crescentic, or disk shaped. Cysts measure 4 to 6 μm in diameter and must be distinguished from erythrocytes. The cysts often occur in clusters within an alveolus.

The typical honeycombed intra-alveolar exudate of *Pneumocystis* pneumonia is largely a collection of interlocking cysts whose walls flatten at points of contact, so that each cyst assumes a hexagonal shape. The internal structure of the silver-stained cyst is variable. In the lighter staining round cysts, a pair of structures about 1 μm long resembling opposed commas or parentheses often are seen; these occasionally are connected end to end by thin, delicate strands [25]. Other cysts contain only a marginal nodule (Fig. 34–1). Whether these intracystic details correspond to the sporozoite-like bodies seen in Giemsa-stained preparations is not clear. Evidence from both light and electron microscopy, however, suggests that they may not be located within cyst cytoplasm at all; instead, they may be thickened portions of the cyst wall [28–30].

Staining procedures, other than those using Giemsa and methenamine silver, have been employed less frequently to delineate the cyst form of the organism. The cyst wall stains red with periodic acid-Schiff stain [31].

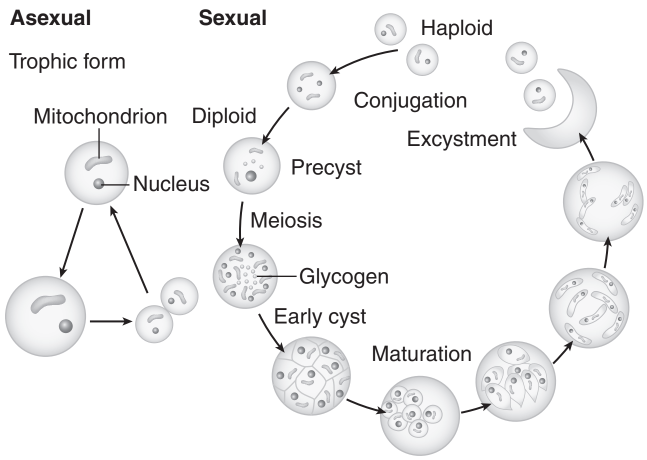

**FIGURE 34–1** Imprint smear of fresh lung tissue stained with methenamine silver shows a cluster of cysts of *Pneumocystis jiroveci*. Typical comma-shaped bodies and marginal nodules are visible within cysts ∞625. *(From Ruskin J, Remington JS. The compromised host and infection. JAMA 202:1070, 1967.)*

A modified Gram-Weigert method stains both the cyst wall and the intracystic sporozoites [32]. Gridley fungus stain may identify cyst outlines. More reliable stains for this purpose are the modified toluidine blue stain of Chalvardjian and Grawe [33] and the crystal violet stain [34], which color the cyst wall purple. Electron microscopy has been an invaluable tool in morphologic studies of *P. jiroveci* [22,29,35–43]. It has helped to confirm that the structures regarded as *Pneumocystis* under light microscopy are, in fact, typical micro-organisms and not just degradation products of host cells [44].

Both trophozoite and cystlike stages have been delineated [43]. The trophozoite is thin walled and measures between 1.5 and 2.0 μm in diameter. It has numerous evaginations or pseudopodia-like projections that appear to interdigitate with those of other organisms in the alveolar space [38,43]. It has been postulated that the pseudopodia make up the reticular framework within which organisms reside in an alveolus, accounting for the fact that organisms remain clumped in lung imprints [24,33]. It also has been suggested that the pseudopodia anchor *Pneumocystis* to the alveolar septal wall [41]. The prevailing opinion, however, is that no specialized organelle of attachment exists. Rather, the surfaces of *P. jiroveci* and alveolar cells (specifically, type I pneumonocytes) are closely opposed, without fusion of cell membranes [45]. This adherence of *P. jiroveci* to alveolar lining cells may explain why organisms are not commonly found in expectorated mucus or tracheal secretions [38].

The classic cystic unit of *P. jiroveci* is thick walled and measures 4 to 6 μm in diameter. The intracystic bodies measure 1.0 to 1.7 μm across and bear a marked similarity to small trophozoites (Figure 34–2) [43]. In addition, thick-walled cysts rich in glycogen particles but without intracystic bodies ("precysts"), partly empty cysts, and collapsed cystic structures have been identified. The collapsed cysts are crescentic and presumably are the same crescentic forms seen frequently in silver-stained specimens under light microscopy. They commonly have defects in their walls.

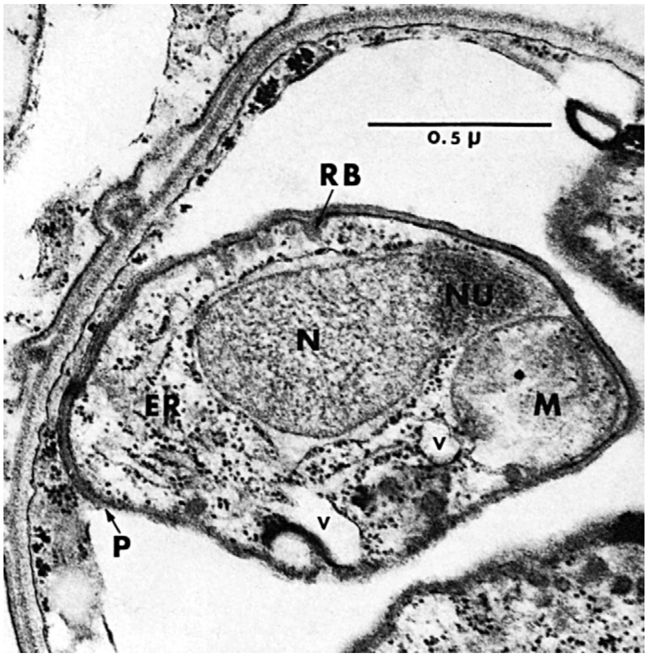

**FIGURE 34–2 Intracystic body within mature cyst.** Six-layer effect of cyst wall occurs only where there is contact with adjacent organisms. Note unit-membrane character of undulating membranes that form innermost layer of cyst wall and outer and inner membranes of pellicle (P). Round bodies (RB) appear to arise from pellicle (*arrow*). Rough endoplasmic reticulum (ER) is well developed. Ribosomes are attached to the external membrane of nucleus, and this membrane appears to communicate with membranes of rough endoplasmic reticulum. Cytoplasm also contains vacuoles (v). Nucleus (N) contains nucleolus (NU). Mitochondrion (M) is at the right. ×80,000. *(From Campbell WG Jr. Ultrastructure of* Pneumocystis *in human lung. Life cycle in human pneumocystosis. Arch Pathol 93:312, 1972.)*

Life cycles for *P. jiroveci* have been proposed. They have been based on the variant forms of the fungus detected by light [29,30,46–48] and electron microscopy [43,49]. One scheme suggests that the thick-walled round cyst undergoes dissolution or "cracking," whereupon the intracystic bodies pass through tears in the wall (Figure 34–3) [43]. It is not known whether the bodies escape from the cyst by active motility or whether they are extruded passively as a consequence of cyst collapse. At this stage, the intracystic bodies resemble free thin-walled trophozoites. It had been suggested that division of the intracystic body must occur soon after its expulsion from the mature, thick-walled cyst, to account for the large numbers of small trophozoites (1 μm in diameter) seen in the infected lung [29]. Electron microscopic observations, however, indicate that another source for the smaller trophozoite is the immature, thin-walled *Pneumocystis* cyst [49]. In any case, the small trophozoites evolve to larger forms, their walls thicken, and a precyst develops that is devoid of intracystic bodies. The cyclic process is completed when formation of the mature cyst, containing eight daughter cysts, is achieved.

Previous controversy over the classification of *Pneumocystis* as a protozoan [50,51] or as a fungus [52] resulted because of the difficulty in cultivating and further characterizing the biochemical nature of the organism. Arguments in favor of a protozoan taxonomy were based mainly on the resemblance of its structural features to those of other protozoa. The organism has cystic and trophozoite stages, pseudopodia in cell walls, and pellicles around intracystic sporozoites [41,53]. In addition, the disease caused by *Pneumocystis* responds to antiprotozoal—namely, antitrypanosomal or antitoxoplasmal—chemotherapy. On the other hand, like fungi, *P. jiroveci* contains a paucity of cellular organelles, its nucleus is not visibly prominent, its cell membrane is layered throughout an entire life cycle, and its cell wall stains vividly with silver [29].

The question of species specificity of *Pneumocystis* remained similarly unanswered until recent polymerase chain reaction (PCR) techniques established that *P. jiroveci* is not found in lung samples from any other mammals [53]. Although most workers concur that human and rodent forms of the organism are morphologically indistinguishable by light and electron microscopy [22,30,43], serologic studies designed to demonstrate identity between human and animal species [28,50] or even between human strains from diverse geographic locales [54,55] yield conflicting results. Genetic analysis, however, clearly demonstrated differences between human and nonhuman *Pneumocystis* isolates [53,56–59].

Successful propagation of *P. jiroveci* in vitro was first reported in 1977 by Pifer and colleagues [60] at the St. Jude Children's Research Hospital. This group of investigators serially passed organisms in primary embryonic chick epithelial lung cells over 12 days and noted a 100-fold increase in the number of cysts. Inoculation of trophozoites alone yielded modest numbers of cyst forms, with typical cytopathogenic effects. Continuing cultivation of *Pneumocystis*, however, was not achieved. In addition, the organisms could not be grown in cell-free media employed commonly for the propagation of other organisms [60]. Limited replication of *Pneumocystis* since has been accomplished in more widely available tissue culture cell lines (Vero, Chang liver, MRC 5, WI 38) [61–64]. These tissue culture systems have not been used to isolate *P. jiroveci* from the lungs of animals or humans with suspected infection. Examination of the organism in tissue culture, however, has confirmed the existence of each of its morphologic forms and has provided insight into the biologic interaction between the organism and the host cells [64].

## EPIDEMIOLOGY AND TRANSMISSION

The natural habitat of *P. jiroveci* is unknown. The distribution of human infection is worldwide [65–90], and a variety of wild and domestic animal species harbor the organism without demonstrable pulmonary disease. Rarely, clinically evident *Pneumocystis* pneumonitis, not unlike the disease in humans, arises spontaneously in the animal host [91–96].

The prevalence of infection with *Pneumocystis* remains to be determined because studies to detect latent carriage of the organism in large populations have not been performed. Serologic surveys, however, indicate that infection is widespread and acquired in early life. Meuwissen and colleagues [97] in the Netherlands noted that immunofluorescent antibodies to *P. jiroveci* are first detectable in

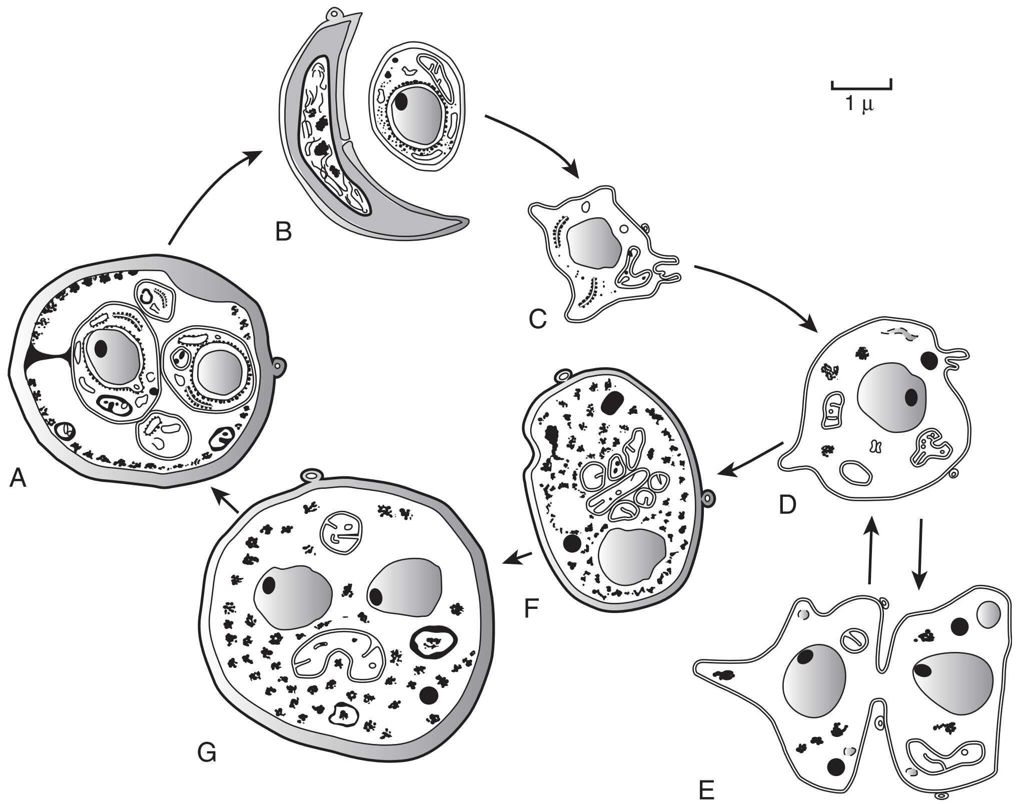

**FIGURE 34–3 Probable life cycle of *Pneumocystis* within pulmonary alveoli. A**, Mature cyst with intracystic bodies; **B**, empty cyst and recently escaped intracystic body; **C**, small trophozoite; **D**, larger trophozoite; **E**, possible budding or conjugating form; **F**, large trophozoite undergoing thickening of pellicle; **G**, precyst. *(From Campbell WG Jr. Ultrastructure of* Pneumocystis *in human lung. healthy children at 6 months of age, and by age 4 years, nearly all children are seropositive. Pifer and associates [98] in the United States found significant titers of antibody to *Pneumocystis* in healthy 7-month-old infants and in two thirds of normal children by age 4 years. Gerrard and coworkers [99] in England detected *P. jiroveci* antibodies in serum from 48% of 94 young healthy children. Pifer and associates [100] also found that serologic evidence of *Pneumocystis* infection is present before immunosuppressive therapy with corticosteroids elicits *Pneumocystis* pneumonia in healthy rats. Authors of a number of autopsy reviews have attempted to determine the incidence of *Pneumocystis* infection, but the results have been divergent, owing to the heterogeneity of the populations studied [87,101–107]. Those studies conducted in central Europe after World War II [102] or in cancer referral centers in the United States [107] have yielded higher rates of infection.

Few published reports have been devoted exclusively to the descriptive epidemiology of *Pneumocystis* pneumonia in the United States. In a literature review of the subject, Le Clair [108] accumulated 107 accounts of the disease recorded from 1955 through 1967. The male-to-female ratio of infected persons was in excess of 2:1, but ethnic distribution was even. The disease was reported from diverse geographic locales (21 of the 50 states). The largest number of cases (33) occurred in infants younger than 1 year of age. Proved or presumptive congenital immunodeficiencies were identifiable in virtually all of the children in this group. In patients 1 to 10 years of age, who constituted the next largest group (26), only six had a primary immune deficit, whereas most of the other children had an underlying hematologic malignancy. The remaining patients, ranging in age from 10 to 81 years, were persons with assorted malignancies or renal allografts who almost always had had prior exposure to corticosteroids, radiation, or cytotoxic drugs. The mortality rate for the entire group of patients was 95%.

The Centers for Disease Control and Prevention (CDC) updated Le Clair's study by investigating the epidemiologic, clinical, and diagnostic aspects of all confirmed cases of pneumocystosis reported to its Parasitic Disease Drug Service between 1967 and 1970 [109,110]. The first of these reports has particular relevance because it focused only on the infectious episodes in infants and young children [109]. A total of 194 documented cases of *P. jiroveci* pneumonia were analyzed, and 29 occurred in infants younger than 1 year of age. The attack rate for this group (8.4 per million) was more than five times higher than that for other age groups. Eighty-three percent of these infants had an underlying primary immunodeficiency disease. Moreover, because the inheritance of the primary immunodeficiency state often was sex linked, the preponderance of infection (88%) occurred in males. The mean age at diagnosis in the immunodeficient infants was 7.5 months, whereas the epidemic form of the

infection in European and Asian infants was associated with peak morbidity in the third and fourth months of life [16,24]. Twenty-four percent of the infected children with immunodeficiencies had at least one sibling with an identifiable immune deficiency in whom *P. jiroveci* pneumonia also developed [109].

After this analysis of cases indigenous to the United States was complete, it became evident that infantile pneumocystosis could be introduced into the United States from epidemics abroad. The first such case was reported in 1966 when a 3-month-old Korean infant died of *Pneumocystis* infection after being brought to the United States from an orphanage in Korea [111]. The potential for imported pneumocystosis received renewed publicity with the cessation of the war in Vietnam. Surveillance for *Pneumocystis* infection in American-adopted Vietnamese orphans was urged when it was recognized that large numbers of infants exposed to the hardships of war and malnutrition in Indochina had experienced fulminant *Pneumocystis* pneumonia [112,113]. In quick succession, multiple cases of *Pneumocystis* infection among these refugee Vietnamese were reported [114–117]. Most of the affected infants were approximately 3 months of age; this was exactly the age at which pneumocystosis had emerged in the marasmic children infected during the earlier nursery epidemics in central Europe and Asia.

The epidemiology of *P. jiroveci* infection has changed as cases of human immunodeficiency virus (HIV) infection have occurred in infants [118]. As is true in adults with acquired immunodeficiency syndrome (AIDS), infants with AIDS are at high risk for this opportunistic infection. Among children with perinatally acquired HIV infection, *P. jiroveci* pneumonitis occurs most often among infants 3 to 6 months of age [119].

It has been suggested [120–124] that *P. jiroveci* may be an important cause of pneumonitis in immunologically intact infants. In a prospective study of infant pneumonia, Stagno and coworkers [124] detected *Pneumocystis* antigenemia in 10 (14%) of 67 infants. None of these 10 infants with serologic evidence of *Pneumocystis* infection had a primary immunodeficiency, nor had any received immunosuppressive medication. Antigenemia did not occur in control infants or in infants with pneumonitis caused by *Chlamydia trachomatis*, respiratory syncytial virus, cytomegalovirus, adenovirus, or influenza A and B viruses. Histopathologic confirmation of *Pneumocystis* pneumonia was possible in the only one of these infants who underwent open lung biopsy. *P. jiroveci* also causes pneumonia in infants living in resource-limited countries, even when the child is not malnourished. Shann and associates [125] found *P. jiroveci* antigen in serum from 23 of 94 children in Papua New Guinea, who were hospitalized with pneumonia. Nevertheless, more cases need to be confirmed histologically before it is established that *Pneumocystis* infection produces morbidity in previously healthy infants.

The mode of transmission of *P. jiroveci* remains unclear. Sporadic cases of pneumocystosis serve as poor models of infection transmission because they may not become clinically manifest until long after the host has acquired the organism. That person-to-person spread of *Pneumocystis* could occur was first suggested by the European nursery epidemics. Even in these institutional outbreaks, however, it was readily appreciated that direct interpatient transfer of the organism happened rarely [16]. Rather, seroepidemiologic investigation indicated that healthy, subclinically infected nursery personnel transmitted the infection [46,54,55]. The mode of spread of *Pneumocystis* from infected asymptomatic persons to susceptible infants in the closed nursery environment is not known. Airborne droplet transmission was suspected when "sterilization of air with ionizing radiation [126]" and isolation of uninfected infants from infected infants and their seropositive attendants [127] reduced the frequency of clinical disease. The hypothesis that *Pneumocystis* is transmissible through the air presupposes that the organism can be found in respiratory secretions. Although, as emphasized earlier, the intra-alveolar histopathologic features of pneumocystosis mitigate against this occurrence, *Pneumocystis* occasionally is detected in tracheal aspirates and sputum [32,47,128–132].

Epidemiologic investigation of sporadic pneumocystosis indicates that person-to-person transmission of the infection is possible. The sequential development of *Pneumocystis* pneumonia in immunosuppressed adults occupying adjoining hospital beds has been recorded [132,133]. Jacobs and associates [134] described a cluster of cases of *P. jiroveci* pneumonia in previously healthy adults who all were hospitalized between July and October 1989. Whereas all five patients were on different floors of this hospital on three different services, two of the patients were briefly in the intensive care unit at the same time. Immunologic evaluation in three of the five patients revealed normal $CD4^+$, $CD8^+$, and $CD4^+/CD8^+$ ratios but depressed responses to T-cell lectin phytohemagglutinin and T cell-dependent B-cell pokeweed mitogen. Occurrence of pneumocystosis among family members also has been reported [121,135,136]. Pneumonia developed in three family members in a strikingly related time sequence [121]. More commonly, cases within a family emerge over a period of several years, and affected members almost always are infant siblings with either proven or suspected underlying immunodeficiencies. In at least three family studies, no fewer than three siblings succumbed to the infection [135,137,138]. It is unlikely, however, that direct patient-to-patient transfer of the organism occurred in any of these settings because in almost all instances, development of disease in the sibling occurred months or years later, often long after the death of the initially infected child [109].

Contagion could still be implicated in the family milieu if a reservoir of asymptomatic infection with *P. jiroveci* existed among healthy family members. Supporting evidence comes from two published accounts of infants with primary immunodeficiencies and pneumocystosis: The parents were deemed to be possible sources of the infection because their sera contained specific anti-*Pneumocystis* antibody [138,139].

Maternal transfer of *Pneumocystis* to infants from colostrum or from the genital tract at parturition also might maintain *Pneumocystis* within a family, but screening of breast milk [136] and cervical secretions [137] with Giemsa and methenamine silver stains has failed to reveal the presence of the organism. Alternatively, acquisition of *P. jiroveci* by infants in utero could occur. Unfortunately,

it is difficult to test this hypothesis in the absence of reliable serologic tools to detect subclinical infection in the newborn. The paucity of documented cases of overt *Pneumocystis* pneumonia in stillborn infants or in the early neonatal period, however, argues against frequent intrauterine passage of the organism.

In 1962 Pavlica [140], in Czechoslovakia, recorded the first instance of congenital infection. The infant described was stillborn. The parents and a female sibling were in good health. The mother's serum had complement-fixing antibodies against *Pneumocystis*. Subsequently, in a report detailing experience with *Pneumocystis* infection in southern Iran, a male child who had died at 2 days of age was described; autopsy examination revealed scattered although definite alveolar foci of typical *Pneumocystis* infection [141]. The authors reasoned that this represented congenital infection rather than an acquired disease with an untenably short incubation period. Bazaz and colleagues [137] in the United States described the striking development of *Pneumocystis* pneumonia in three otherwise healthy female siblings who died at 3 months, 2 months, and 3 days of age, respectively; again, an in utero source for their infections was considered to be most likely. In none of these cases of presumptive congenital pneumocystosis, however, was the placenta examined histologically for the presence of the organism. One infant, born to a mother with AIDS and documented *P. jiroveci* pneumonia in the fourth month of gestation, did not have *P. jiroveci* infection in the newborn period [142]. Beach and coworkers [143] described an HIV-positive newborn with meconium aspiration and pneumonia who had *P. jiroveci* identified in lung biopsy material at 19 days of age. Despite the infant's positive HIV status, serum from the infant's mother was HIV negative, and the serum from the father was HIV positive. Because the parents disappeared shortly after the infant's birth, follow-up evaluation was not possible; however, the parents had no previous history of *P. jiroveci* pneumonia, and the mother had been noted to be markedly wasted.

The mode of transmission of *Pneumocystis* in older children was first explored in the United States at the University of Minnesota Hospitals [144] and at St. Jude Children's Research Hospital [107], where an unusually high number of cases was recorded. At neither center was it possible to reconstruct the spread of pneumocystosis from one patient to another. In most cases, the onset of illness appeared to antedate admission to the hospital. No attempt was made to incriminate healthy carriers as point sources for seemingly isolated episodes of infection. At Memorial Hospital in New York, *Pneumocystis* pneumonia developed in 11 patients, including 6 children, over a 3-month period [145]. Although no definite evidence of communicability could be discerned in this statistically significant cluster of cases, several of the *Pneumocystis*-infected children had had contact with each other and had shared rooms at various times; in addition, results of serologic tests for *Pneumocystis* infection were positive in two physicians caring for these patients. Similar outbreaks have since occurred in two pediatric hospitals in Indianapolis [146] and Milwaukee, Wis [147]. At these centers, the increased rates of pneumocystosis were clearly related, as they were at St. Jude Children's Research Hospital [107,148], to the use of more intensive cancer chemotherapy regimens. In a seroepidemiologic investigation of the cases in the Indianapolis outbreak, however, it was found that transmission of *Pneumocystis* probably occurred within the hospital environment. A direct association was noted between duration of hospitalization and risk of subsequent *Pneumocystis* infection. Furthermore, a significantly higher prevalence of positive results on serologic testing for *Pneumocystis* was detected among staff members who had close contact with infected children than among personnel whose duties did not include such patient contact. Precisely how *Pneumocystis* was originally introduced into the hospital was not determined.

The possibility that *Pneumocystis* pneumonia is a zoonotic disease and that infestation of rodents or even domesticated pets could provide a sizable reservoir for human infection has been investigated to a limited degree. Abundant infection of rodents with *Pneumocystis* was discovered in patients' homes in many of the index cases in ward epidemics in Czechoslovakia [149]. At St. Jude Children's Research Hospital, a high rate of exposure to pets was noted among the *Pneumocystis*-infected children with malignancy [150]. Of course, these findings would have epidemiologic significance only if the species of *Pneumocystis* infecting both animals and humans was the same. This remains to be shown. Experimental attempts to produce clinical pneumocystosis in multiple animal species by inoculation of infected human lung suspensions have not been successful [151–153] unless the animal was congenitally athymic [154] or immunosuppressed by treatment with corticosteroids [155].

Airborne transmission of *Pneumocystis* was first presumptively demonstrated by Hendley and Weller in 1971 [153]. These investigators observed that in cesarean section-obtained, barrier-sustained (COBS) rats given corticosteroids, infections with *Pneumocystis* developed following exposure to a common air supply from standard infected rats, whereas control COBS animals that received corticosteroids remained free of infection. One potential flaw in this experimental design was that the corticosteroid therapy could have reactivated previously latent *Pneumocystis* infection in any of the challenged animals. To circumvent this problem, Walzer and coworkers [151] challenged congenitally athymic (nude) mice. These animals received no exogenous immunosuppressants and still contracted pneumocystosis after exposure to air from infected rats. Thus, these studies documented airborne transmission of *P. jiroveci* and spread of the organism between different animal species. Of note is that soon after these experiments were published, a natural epizootic of *Pneumocystis* pneumonia was uncovered in a colony of nude mice [154]. Other studies using the murine model of pneumocystosis have suggested that subclinical transmission of the infection also can occur. Healthy rats exposed to animals with *Pneumocystis* pneumonia remain well but are found to have titers of anti-*Pneumocystis* antibodies consistent with acute acquisition of the infection [155]. In addition, rats with pre-existing *Pneumocystis* antibodies may become antigenemic on comparable exposure to overt infection; these animals may be experiencing subclinical reinfection [100].

## PATHOLOGY

The gross and microscopic pathologic features of *P. jiroveci* pneumonia have been elucidated in a number of excellent reviews.* At autopsy in typically advanced infection, both lungs are heavy and diffusely affected. The most extensive involvement often is seen in posterior or dependent areas. At the lung margins anteriorly, a few remaining air-filled alveoli may constitute the only portion of functioning lung at the time of death [11]. Subpleural air blebs not infrequently are seen in these anterior marginal areas. Occasionally, prominent mediastinal emphysema or frank pneumothorax can be noted. The color of the lungs is variously described as dark bluish purple [24,141], yellow-pink [25], or pale gray-brown [11,27]. The pleural surfaces are smooth and glistening, with little inflammatory reaction. Hilar adenopathy is uncommon. Necrosis of tissue is not a feature of the disease.

Although these gross features of widespread infection are strikingly characteristic, focal or subclinical pneumocystosis presents a less recognizable picture. In this condition, the lung has tiny 3- to 5-mm reddish brown retracted areas contained within peribronchial and subpleural lobules, where hypostasis is greatest [24,31]. Even these features, however, may be absent because of variable involvement of adjacent lung tissue by concomitant pathologic processes.

The microscopic appearance of both the contents and the septal walls of pulmonary alveoli in *Pneumocystis* pneumonia are virtually pathognomonic of the infection. The outstanding histologic finding with hematoxylin and eosin stain is an intensely eosinophilic, foamy, or honeycomb-like material uniformly filling the alveolar sacs (Figure 34–4). This intra-alveolar material is composed largely of packets of *P. jiroveci* [126,159]. Typical cysts or trophozoite forms of the organism within alveoli are visible only after application of special stains such as methenamine silver.

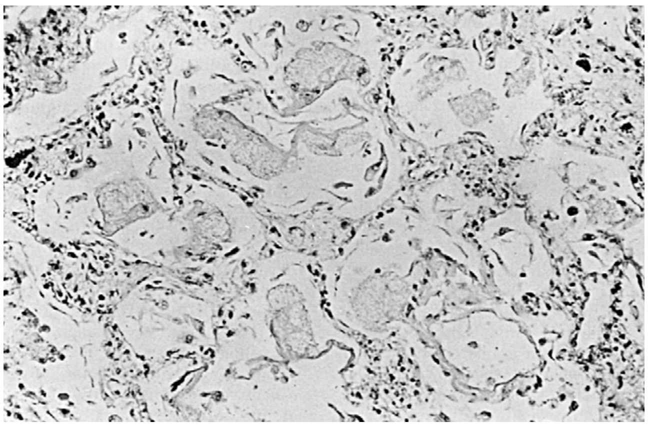

**FIGURE 34–4** Section of lung tissue obtained at autopsy showing the amorphous, proteinaceous intra-alveolar infiltrate characteristic of pneumonitis caused by *Pneumocystis jiroveci*. Hematoxylin and eosin stain, ×160. *(From Remington JS. The compromised host. Hosp Pract 7:59–70, 1972.)*

*References [11,16,24,27,32,126,144,156–158].

The type and degree of cellular inflammatory response provoked by the intra-alveolar cluster of *Pneumocystis* organisms vary in different hosts [126]. The descriptive histologic term for pneumocystosis—interstitial plasma cell pneumonia—is derived from the pronounced plasma cellular infiltration of the interalveolar septa observed almost exclusively in newborns in European nursery epidemics. Distention of alveolar walls to 5 to 10 times the normal thickness, with resultant compression of alveolar spaces and capillary lumens, typically is noted in this form of the disease. Hyaline membranes develop occasionally [11], often when the foamy honeycomb pattern within alveoli is least prominent [144]. Septal cell hyperplasia is apparently a nonspecific reaction of lung tissue to injury induced by infections of diverse etiology [160].

Hughes and colleagues [150] studied the histologic progression of typical *Pneumocystis* pneumonia based on the number and location of organisms and the cellular response in pulmonary tissue. The lung samples were from children with underlying malignancy who had received intensive chemotherapy. The authors categorized three sequential stages in the course of the disease. In the first stage, no septal inflammatory or cellular response is seen, and only a few free cyst forms are present in the alveolar lumen; the remainder are isolated in the cytoplasm of cells on the alveolar septal wall. The second stage is characterized by an increase in the number of organisms within macrophages fixed to the alveolar wall and desquamation of these cells into the alveolar space; again, only minimal septal inflammatory response is seen at this time. Finally, a third stage is identified in which extensive reactive and desquamative alveolitis can be seen. Such diffuse alveolar damage may be the major pathologic feature in certain cases [161]. Variable numbers of cysts of the organism, presumably undergoing dissolution, are present within the alveolar macrophages. These findings underscore an earlier claim [162] that the so-called foamy exudate within alveoli is neither foamy edema fluid nor the product of an exudative inflammatory reaction but largely a collection of coalesced alveolar cells and macrophages that contain sizable digestive vacuoles and remnant organisms.

The mechanism of spread of *Pneumocystis* throughout pulmonary tissue is not completely understood. Direct invasion by the organism through septal walls into the interstitium or the lymphatic or blood vascular spaces of the lung is considered unlikely [31,144,150], except in rare instances when systemic dissemination of the organism occurs (see later discussion). Instead, it is probable that coughing expels cysts from the alveoli into larger airways and that the organisms are then inhaled into previously uninvolved alveolar areas [126]. This hypothesis of interairway transfer of *Pneumocystis* is supported by the fact that the heaviest concentration of organisms usually is found in dependent portions of the lung parenchyma.

Interstitial fibrosis is a distinct but infrequently reported complication of *Pneumocystis* pneumonia in older children and adults but has been reported in infants only rarely [12,144,157,158,163–169]. Nowak [166], in Europe, first emphasized that fibrosis was not unusual in the lungs of infants at autopsy who had especially protracted infection with *P. jiroveci*. *Pneumocystis*-infected

lungs sometimes demonstrate, in addition to fibrosis, other pathologic features compatible with a more chronic destructive inflammatory process. Multinucleate alveolar giant cells occasionally accompany alveolar cell proliferation [24,27,31,158]. Whether presence of these cells is more often a response to undetected concomitant viral infection is unknown. Typical granulomatous reactions with organisms visible in the granulomas also have been described [158,170,171]. Extensive calcification of *Pneumocystis* exudate and adjacent lung tissue may ultimately develop [27,144,158].

## PATHOGENESIS

The clinical conditions that predispose patients to the development of *Pneumocystis* pneumonia are associated with impaired immune responses, leading to the presumption that *Pneumocystis* causes disease not because it is intrinsically virulent but because the host's immune mechanisms fail to contain it (Table 34–1). The severity of *P. jiroveci* pneumonia in infants with AIDS illustrates this phenomenon dramatically. The primary role of immunocompromise also would explain in part why *Pneumocystis* pneumonia did not emerge as a serious health problem until more than 30 years after the disease was first recognized. European epidemics of *Pneumocystis* arose out of the devastation of World War II and widespread use of antibacterial drugs. Each of these two seemingly unrelated events served ultimately to disrupt the normal host-organism immunologic interaction in favor of the organism. The war resulted in institutionalization of inordinate numbers of orphans under conditions of overcrowding and malnutrition. At the same time, antibacterial therapy dramatically enhanced survival rates of these institutionalized infants, who would otherwise have succumbed to bacterial sepsis during the first days or weeks of life. In addition, it was realized that *Pneumocystis* infection appeared in these marasmic children at an age when their immunoglobulin G levels reached a physiologic nadir. By 1960, the orphanage epidemics had abated in Europe as environmental conditions improved, but they persisted in Asia, where poverty and overcrowding continued [141,172]. Subsidence of the epidemic disease and more widespread antibacterial drug therapy, along with sophisticated immunosuppressive drug treatment, contributed thereafter to awareness in Europe and North America of isolated instances of *Pneumocystis* infection among children suffering from a variety of identifiable immunodeficiencies.

**TABLE 34–1** Conditions Associated with *Pneumocystis jiroveci* Pneumonia

1. Premature infants aged 2 to 4 months with marasmus and malnutrition, usually living in foundling homes in geographic locales endemic for pneumocystosis
2. Infants and children with congenital (primary) immunodeficiency disease
   a. Severe combined immunodeficiency
   b. X-linked agammaglobulinemia
   c. X-linked immunodeficiency
   d. Variable immunodeficiency
   e. Immunodeficiency with hyperimmunoglobulinemia
   f. Immunodeficiency associated with Wiskott-Aldrich syndrome
3. Children and adults with acquired immunodeficiency
   a. Disease-related: lymphoreticular malignancies; multiple myeloma; dysproteinemias
   b. Drug-related (corticosteroids, cyclophosphamide, busulfan, methotrexate, colloidal gold); organ transplantation; lymphoreticular malignancies; solid tumors; collagen vascular disorders; miscellaneous diseases treated with immunosuppressants
   c. Acquired immunodeficiency syndrome (human immunodeficiency virus infection)

*Adapted from Burke BA, Good RA.* Pneumocystis carinii *infection. Medicine 52:23, 1972; Walzer PD, et al.* Pneumocystis carinii *pneumonia in the United States; epidemiologic, diagnostic and clinical features. Ann Intern Med 80:83, 1974, with permission.*

Weller, in Europe, was among the first to experimentally induce *Pneumocystis* pneumonia in animals [173,174]. His crucial observation relative to pathogenesis of the infection was that in rats pretreated with cortisone (and penicillin) and exposed to suspensions of *Pneumocystis*-containing lung tissue, *Pneumocystis* pneumonia develops with the same frequency and severity as in corticoid-treated animals that were not subsequently inoculated with organisms. The intensity of such artificially induced animal infection also was noted to be less marked than that in spontaneous human pneumocystosis of the epidemic variety. Comparable observations in the rabbit model were made by Sheldon in the United States [152]. He showed that cortisone and antimicrobial agents were sufficient to induce *Pneumocystis* infection without direct exposure of animals to an exogenous source of organisms. The inescapable conclusion of these carefully designed studies was that *Pneumocystis* infection is latent in rats and rabbits and becomes clinically manifest only when host resistance is altered.

In 1966, Frenkel and colleagues [175] published a hallmark study of rat pneumocystosis. They showed that clinical and histopathologically significant involvement with *Pneumocystis* is regularly inducible in rats by "conditioning" them with parenteral cortisone over a period of 1 to 2 months. Premature death from complicating bacterial infection was prevented by simultaneous administration of antibacterial agents. Of interest is their finding that regression of established interstitial pneumonitis occurs if cortisone conditioning is stopped early enough; on the other hand, rats continuing to receive cortisone die of coalescent alveolar *Pneumocystis* infiltration, and the infiltrate is almost devoid of inflammatory cells. These histologic changes are, in fact, an exact replica of those observed in sporadic cases of human *Pneumocystis* infection developing in congenitally immunodeficient and exogenously immunosuppressed patients. Those authors attempted to precipitate clinical pneumocystosis with a variety of immunosuppressants other than cortisone. Of eight cytotoxic agents and antimetabolites tested, only cyclophosphamide was shown to activate latent infection. Total-body irradiation and lymphoid tissue ablation (splenectomy, thymectomy) by themselves were incapable of inducing overt *Pneumocystis* pneumonia.

The clinical association between pneumocystosis and protein-calorie malnutrition also has been reproduced in a rat model [176]. Healthy rats given either a regular or a low-protein diet gain weight and exhibit little to no evidence of pneumocystosis post mortem. By contrast,

in rats fed a protein-free diet, which produces weight loss and hypoalbuminemia, fatal infection regularly developed; administration of corticosteroid only foreshortened their median survival time [170].

None of the experimental models described thus far permit a precise appraisal of the relative importance of the cellular and humoral components of host defense against *Pneumocystis*. Although corticosteroids, cytotoxic drugs, and starvation interfere primarily with cell-mediated immunity, they do not always induce purely functional cellular defects. For example, it is known from in vitro cell culture studies that corticosteroids do not inhibit the uptake of *Pneumocystis* by alveolar macrophages [64]. Rather, the immunosuppressive effects of chemotherapeutic agents or of malnutrition are far more complex, and ultimately both cellular and humoral arms of the immune system may be impaired by them.

The production of pneumocystosis in the nude mouse without the use of exogenous immunosuppressants implies that susceptibility to the infection relates most to a defect in thymic-dependent lymphocytes [151]. Antibody deficiency must be less important because certain strains of nude mice are resistant to pneumocystosis, yet neither these animals nor their susceptible littermates produce measurable antibodies. These findings do not exclude a role for antibody in control of established infection with the organism; indeed, it has been shown in vitro that *P. jiroveci* organisms adherent to rat alveolar macrophages become interiorized only after anti-*Pneumocystis* serum is added to the culture system [155].

That primary immune deficits could predispose to sporadic pneumocystosis was first reported, unwittingly, by Hutchison in England in 1955 [85]. He described male siblings with congenital agammaglobulinemia who died of pneumonia of "similar and unusual" histology. *P. jiroveci* was implicated as the etiologic agent of these fatal infections only when the pathologic sections were reviewed by Baar [177], who had reported the first case of *Pneumocystis* pneumonia in England earlier that year [71]. In one of the first such reports from the United States, Burke and her colleagues [178] stressed what was to be regarded as a typical histologic finding in *Pneumocystis*-infected agammaglobulinemic children—namely, the absence or gross deficiency of plasma cells in pulmonary lesions (and in hematopoietic tissues). This deficiency contrasted sharply with the extensive plasmacytosis seen in epidemic infections. In addition, sera from some of these hypogammaglobulinemic children did not contain antibody to a *Pneumocystis* antigen derived from lung tissue in "epidemic" European cases [55].

None of these *Pneumocystis*-infected patients with a primary humoral immunodeficiency disease had evidence of an isolated impairment of cellular immunity. (Indeed, only once has pneumocystosis been reported in association with a pure T cell deficiency—namely, in DiGeorge's syndrome [179]). Most of the *Pneumocystis* infections, however, did occur in the infants with severe combined immunodeficiency, a state characterized by profound depression of both cellular and humoral immunity.

That the integrity of the cellular immune system is critical for resistance to *Pneumocystis* may be inferred from the steroid-induced and congenitally athymic animal models of pneumocystosis described earlier and from clinical experience with the infection in older children with lymphoreticular malignancies, collagen-vascular disorders, or organ allografts. These individuals receive broad immunosuppressive therapy designed to inhibit mainly the cellular arm of the immune system. Indeed, the incidence of *Pneumocystis* infection in these patients is related less to the nature of the underlying condition than to the intensity of immunosuppressive chemotherapy given for it [126,144,148,160,180–182].

For many years it had not been possible to study in vitro the cellular immune response to *P. jiroveci* because of the impurity of available antigens. Preliminary experiments with an antigen derived from a cell culture suggested that specific cell-mediated immunity may be depressed in children with active *Pneumocystis* pneumonia. Lymphocytes from two such children failed to transform in the presence of the antigen [183], whereas lymphocytes from healthy, seropositive adults were in most cases stimulated specifically to undergo blastogenesis [183,184].

The humoral immune response to pneumocystosis has been measured in a variety of infected populations.* The most detailed serosurveys have been conducted in Iran [24,187] and central Europe [188–190] in infants with typical epidemic interstitial plasma cell pneumonia. Infants in Iranian orphanages had elevated levels of all immunoglobulins presumably because of the abundance of infective organisms in their institutional environments compared with values recorded in age-matched healthy U.S. infants [187]. No statistical difference was detectable in immunoglobulin concentrations between *Pneumocystis* carriers (those with "focal pneumocystosis") and uninfected infants within an orphanage. Prominent elevation in serum IgM levels correlated with the intensity of *Pneumocystis* disease as measured by clinical, radiographic, and histologic (e.g., plasma cell infiltration) criteria. The peak values of IgM persisted for only a short "crisis" period and then rapidly decreased toward normal. Serum IgG concentrations reached significantly depressed values of less than 200 mg/dL only in infants with massive interstitial pneumonitis. A precipitous drop in serum IgA level was recorded in three *Pneumocystis*-infected children 2 to 3 days before onset of marked respiratory impairment; the complete absence of alveolar IgA also was documented by fluorescent antibody techniques.

Iranian workers have proposed a provocative hypothesis relating these alterations in immunoglobulin levels to the pathogenesis of infant pneumocystosis. The level of transplacentally transferred maternal anti-*Pneumocystis* IgG decreases during the infant's first months of life. This reduction may be accentuated and occur earlier in premature infants, owing in part to malnutrition, diarrhea, and inordinate gastrointestinal protein loss [24,187,191,192]. This low IgG concentration probably predisposes these infants to intra-alveolar proliferation of *P. jiroveci*. Normally, IgA prevents surface spread of the organism. If serum IgA levels also are low, so that bronchoalveolar IgA secretion ceases (this remains to be proved), surface spread of the infection proceeds. Subsequently, progression of

*References [109,144,150,157,185,186].

focal pneumocystosis to clinically evident pneumonia occurs. Increased IgM antibody formation reflects a humoral response to the highly antigenic cyst walls of the organism. If the infant survives, active production of *Pneumocystis*-specific IgG occurs during the fifth to ninth month of life. Patients with "hypoimmune pneumocystosis," so named by Dutz [24], with underlying congenital immunodeficiency (or acquired immune defects from immunosuppressive chemotherapy) would not exhibit such an IgG response and thus would be subject to recurrence of clinically manifest pneumonic disease. An obstacle to complete acceptance of this hypothesis is that it assigns a major role to IgG and IgA in host defense against *P. jiroveci* infection. Yet *Pneumocystis* pneumonia has not been reported in children who produce little or no IgA, such as those with ataxia-telangiectasia [144].

Brzosko and his colleagues [188–190,193] in Poland have studied the immunopathogenesis of *Pneumocystis* pneumonia at the tissue level by immunofluorescent methodology. These investigators first reported that $\gamma$-globulin is present in the intra-alveolar exudate of *Pneumocystis* infection [193]. Subsequently, they demonstrated that this collection of $\gamma$-globulin represents the specific antibody component of *Pneumocystis* antigen-antibody complexes [189]. Direct immunofluorescent staining of infected lung tissue with fluorescein-conjugated antihuman globulin or rheumatoid factor revealed a large amount of "immune" globulins bound to packets of *Pneumocystis*. In the same infected tissue blocks, immunofluorescent complement fixation reactions also resulted in marked fluorescence of *Pneumocystis*-$\gamma$-globulin complexes. The avidity of these conglomerates for rheumatoid factor and complement supports the assumption that the tissue-bound $\gamma$-globulin deposits are specific immune reactants to *P. jiroveci* [189]. The most intense fluorescence coincided with periodic acid-Schiff-positive structures (presumably glycoproteins or mucoproteins) on the outer aspect of thick-walled cysts, suggesting that the major antigenicity of the organism resides in its mucoid envelope [188].

Polish workers attempted to reconstruct the immunomorphologic events in typical epidemic pneumocystosis [190]. In the earliest stage of infection, the antigenic constituents of *P. jiroveci* induce the formation of IgM and IgG anti-*Pneumocystis* antibodies, possibly in hilar and mediastinal lymph nodes. These antibodies bind to aggregates of alveolar *Pneumocystis* to form immune complexes. The latter then bind complement, with resultant gradual disintegration of the masses of organisms and their eventual phagocytosis by alveolar macrophages. Immunoglobulin-forming plasma cells proliferate in the interstitium and, conceivably, contribute additional antibody to the *Pneumocystis* aggregates. Clearly, no impairment in immunoglobulin synthesis is recorded in this analysis of epidemic pneumocystosis, but retarded binding of complement components to the immune complexes is regularly observed. Because the ultimate destruction and removal of the *Pneumocystis*-antibody conglomerates are complement dependent and the complement system is, in general, physiologically deficient in the first few months of life, survival of a particular infant with epidemic *Pneumocystis* pneumonia may depend on the stage of development and relative functional competency of the complement system.

# CLINICAL MANIFESTATIONS

## General Considerations

No clinical features are pathognomonic for *P. jiroveci* infection. Organisms residing in scattered intra-alveolar foci may evoke no illness [31,194,195], whereas histologically advanced infection may provoke variable symptoms and signs in different hosts. Features attributable to *Pneumocystis* infection per se may be obfuscated by concomitant infection with other opportunistic pathogens or by dramatic complications of an underlying condition [27,185]. Furthermore, clinical syndromes ascribable to *Pneumocystis* may be simulated by other infections (cytomegalovirus [16], or by inflammatory processes (drug-induced pulmonary toxicity [196], radiation fibrosis [197] and neoplasia (pulmonary leukemia [198] capable of producing interstitial pulmonary infiltrates in older children and adults. Thus, recognition of pneumocystosis on clinical grounds requires above all a high index of suspicion whenever interstitial pneumonia occurs in settings known to predispose to infection with the organism.

Despite these caveats, *Pneumocystis* is distinguishable from other opportunistic microbes by the fact that infection with this organism commonly surfaces when underlying disorders are quiescent. For example, in the case of severe combined immunodeficiency disease, pneumocystosis can develop only after immunologic competence has been at least partially restored by bone marrow transplantation [109,144,199]. Reversal of immune paralysis apparently elicits sufficient inflammation to convert subclinical infection to overt pneumonitis. Similarly, in children with lymphocytic leukemia, pneumocystosis most often occurs during periods of clinical and hematologic remission [145,150,200–203]. It may be inferred from these observations that pneumocystosis is not merely an end-stage infection in a host with a preterminal illness but, on the contrary, often represents a potentially treatable cause of death in patients whose primary immunodeficiency or malignancy has been controlled or effectively cured.

## Symptoms and Signs

### *Epidemic Infection in Infants*

The onset of epidemic types of infection in infants is reported to be slow and insidious. Initially, nonspecific signs of restlessness or languor, poor feeding, and diarrhea are common. Tachypnea and periorbital cyanosis gradually develop. Cough productive of sticky mucus, although not prominent, may appear later [16,31]. Respiratory insufficiency progresses over 1 to 4 weeks, and patients exhibit increasingly severe tachypnea, dyspnea, intercostal retractions, and flaring of the nasal alae. Fever is absent or of low grade [204]. Physical findings are strikingly minimal and consist primarily of fine crepitant rales with deep inspiration. Chest roentgenograms, however, typically demonstrate pulmonary infiltrates early in the illness. The duration of untreated disease is 4 to 6 weeks, but it often is difficult to determine an exact date of onset of illness. Before the introduction of pentamidine therapy, the mortality rate for such epidemic infant infection is estimated to have been between 20% and 50% [72,186].

### *Sporadic Infection in Infants*

The typical clinical syndrome is less evident in sporadic cases of pneumocystosis occurring in infants with acquired or congenital immunodeficiency and in older children with acquired immunodeficiency. In infants with primary immunodeficiency diseases, the onset of clinical infection can be insidious, and illness can extend over weeks or possibly months [144], a course not unlike that seen in epidemic pneumocystosis. By contrast, in most infants with congenital immunodeficiency or AIDS and in older children with acquired immune deficits, *Pneumocystis* pneumonia manifests abruptly and is a more symptomatic, short-lived disease [42,105,110,144,150]. Among infants with HIV infection, the median age at onset is 4 to 5 months, and the mortality rate is between 39% and 59% [205]. High fever and nonproductive cough are initial findings, followed by tachypnea, coryza, and, later, cyanosis. Death may supervene within a week or so. If no treatment is given, essentially all patients with this form of pneumocystosis die.

## Radiologic Findings

Because the extent of pulmonary involvement in *P. jiroveci* pneumonia rarely is detectable by physical examination, a chest roentgenogram showing diffuse infiltrative disease is the most useful indicator of infection in a susceptible host [42,206]. Although certain characteristic patterns of radiographic involvement have been ascribed to *Pneumocystis* pneumonitis, it is worth emphasizing that the findings may vary depending on the presence of coincident pulmonary infection and on the nature of the underlying disease state.

### *Epidemic Infection in Infants*

Ivady and colleagues [186] in Hungary studied the radiographic progression of epidemic infantile *Pneumocystis* pneumonia and identified five stages. The first three stages are recognizable when the infant is virtually symptom free and are defined by the presence of perivascular and peribronchial peripheral shadows extending toward the pleura. The two later stages more closely coincide with respiratory insufficiency and reveal changes resembling "butterfly" pulmonary edema and peripheral emphysematous blebs. The radiographic findings of mild ("focal") *Pneumocystis* pneumonia described by Vessal and associates [207] in infants from an Iranian orphanage included hilar interstitial infiltrate, thymic atrophy, pulmonary hyperaeration, and scattered lobular atelectasis. Although none of these signs is specific for *Pneumocystis* infection, they persist longer (3 weeks to 2 months) in serologically proven cases. Indeed, surviving infants may exhibit focal interstitial infiltrates after organisms are cleared from the lung [208] and for as long as 1 year [204,209].

### *Sporadic Infection in Infants*

A majority of radiologic characterizations of *Pneumocystis* pneumonia have emphasized the sporadic form of the infection. Minor differences in descriptive details usually reflect differences in the populations studied [144,169,210–214]. In infants, especially those with immunodeficiency syndromes, the initial roentgenogram often shows haziness spreading from the hilar regions to the periphery, which assumes a finely granular, interstitial pattern. An antecedent gross alveolar infiltrate usually is not seen [144]. The peripheral granularity may progress to coalescent nodules. These changes resemble the "atelectatic" radiographic abnormalities of hyaline membrane disease. In both conditions, aeration is absent peripherally. Pneumothorax with subcutaneous and interstitial emphysema and pneumomediastinum are not uncommon and are associated with a poor prognosis [215]. Even with therapy, radiographic clearing can lag far behind clinical improvement.

As experience with *Pneumocystis* has broadened, especially in older children and adults, a number of atypical roentgenographic abnormalities have been described [42,213,214,216–223]. These atypical findings include hilar and mediastinal adenopathy, pleural effusions, parenchymal cavitation, pneumatoceles, nodular densities, and unilateral or lobar distribution of infiltrates. By contrast, the chest roentgenographic appearance can remain essentially normal well after the onset of fever, dyspnea, and hypoxemia. The presence of such roentgenographically silent lung disease can be visualized as abnormal findings by pulmonary computed tomography.

## Laboratory Studies

Routine laboratory studies yield little diagnostic information in *Pneumocystis* infection. Abnormalities in hemoglobin concentration or white blood cell count are more likely to result from an underlying disease of the hematopoietic system or cytotoxic drug effect. Neither laboratory value is consistently altered by secondary pneumocystosis. Nevertheless, a subgroup of infants with primary immunodeficiency disease and infection caused by *P. jiroveci* can exhibit significant eosinophilia [31,72,138,144]. Jose and associates [138] first emphasized the association of peripheral blood eosinophilia and pneumocystosis in a report describing three infected male siblings with infantile agammaglobulinemia. In one of the infants, eosinophilia developed very early in the course of the illness, and the differential eosinophil count peaked at 42% as the respiratory disease worsened. Accordingly, it has been suggested that the combination of cough, tachypnea, diffuse haziness on chest roentgenograms, and eosinophilia in an infant with immunodeficiency can be indicative of *Pneumocystis* pneumonia [138,144]. Hypercalcemia with or without nephrocalcinosis has been reported in infants with epidemic pneumocystosis [72]. Measurement of serum calcium levels in other patients with *Pneumocystis* infection, however, has revealed normal values whether or not coincident foci of pulmonary or renal parenchymal calcification existed [105,144,150].

A constant pathophysiologic finding in pneumocystosis, and in other interstitial pulmonary diseases, is that of ventilation and perfusion defects most compatible with an "alveolar-capillary block" syndrome.* Arterial blood gas determinations in infected patients show severe hypoxemia and hypocapnia, often before profound subjective respiratory insufficiency or even radiologic abnormalities

*References [120,125,144,180,185,224–227].

[228] supervene. Less commonly, modest hypercapnia with respiratory acidosis is recorded [224]. This respiratory pathophysiology correlates well with the anatomic pulmonary lesion in *Pneumocystis* pneumonia. Concentration of organisms within alveoli and inflammation of the surrounding alveolar septa not unexpectedly lead to interference in gas transfer, whereas persistence of areas of normal lung parenchyma and lack of significant airway obstruction account for the usual absence of carbon dioxide retention.

## Concurrent Infection

The clinical presentation of pneumocystosis may be altered by simultaneous infection with other organisms. Certainly, infection with a variety of opportunistic pathogens is not surprising in patients with broadly compromised immunologic defense mechanisms. Infection with one or more organisms was found in 56% of *Pneumocystis*-infected infants and children with primary immunodeficiency disease reported to the CDC [109]. Comparable rates of multiple infections also have been noted in several large series of patients with acquired immune defects and pneumocystosis [21,144,160,229].

Infection with cytomegalovirus appears to be the most common "unusual" infection associated with pneumocystosis. Indeed, in his 1957 review, Gajdusek [16] already was able to cite numerous published studies referring to the "unexpectedly high frequency of association" of the two infections. He conceded that one infection most probably predisposed the affected patient to the other. On the basis of electron micrographic observations of cytomegalovirus-like particles within pneumocysts, Wang and coworkers [39] hypothesized that *P. jiroveci* may even serve as an intermediate host or reservoir of the virus. The possibility of viral parasitism of (or symbiosis with) *Pneumocystis* also was explored by Pliess and Seifert [230] and by Vawter and colleagues [40], who were impressed by the resemblance of the outer membranes of *P. jiroveci* to an imperfect form of myxovirus. It is still unclear, however, whether this inordinate concurrence of *Pneumocystis* and cytomegalovirus is caused by a specific and unique relationship between the two organisms or by coincidental infection of highly susceptible hosts with ubiquitous microbes [160,231]. Histopathologic examination of lung biopsy specimens from infants with AIDS often demonstrates concomitant cytomegalovirus and *P. jiroveci* infections [232,233].

# DIAGNOSIS

The diagnosis of *Pneumocystis* pneumonia remains difficult. The organism must be visualized in the respiratory tract of ill persons, and often this can be accomplished only by bronchoalveolar lavage (BAL) or, in infants, a lung biopsy. Recently, PCR assay has been used for diagnosis in fluid specimens obtained by BAL. Nevertheless, this technique is still not sensitive and specific enough for routine clinical use. Attempts to isolate *Pneumocystis* from clinical specimens on synthetic media or in tissue culture have not been successful, and serologic techniques to detect active infection have been too insensitive.

## Examination of Pulmonary Secretions

During the European epidemics, parasitic forms were recognized in mucus from infected infants [32,48,129]. Specimens usually were obtained through a catheter or laryngobronchoscope passed into the hypopharynx, and smears of the aspirated secretions were fixed in ether-alcohol and stained by the Gram-Weigert technique. By this method, Le Tan-Vinh and associates [32] in France reported antemortem diagnosis of *Pneumocystis* pneumonia in eight of nine infants. Toth and coworkers [129] in Hungary recovered *P. jiroveci* from tracheopharyngeal and gastric aspirates of 22 infants whose illness had just begun; in some cases, organisms were observed 7 to 10 days before the appearance of symptoms. The mere presence of organisms in hypopharyngeal secretions, however, did not always presage acute pneumonic disease in these environments, where pneumocystosis was endemic. Rather, it often reflected chronic subclinical carriage of the organism [24].

Diagnosis of sporadic cases of pneumocystosis by examination of sputum or tracheal and gastric aspirates has never been as rewarding. The rate of recovery of *Pneumocystis* from upper airway secretions in the cases compiled by the CDC was estimated to be only about 6% [110]. Japanese investigators have described a method of concentrating sputum samples with acetyl-L-cysteine in 0.2N sodium hydroxide solution, which permits filtration and centrifugation of a pellet of *Pneumocystis* [234]. Ognibene and associates [235] reported the use of induced sputa in the diagnosis of pneumonia in 18 children with HIV infection or malignancy. Nine sputum samples were positive for *P. jiroveci* by immunofluorescent antibody testing. Four of the patients with negative findings by examination of sputum samples subsequently underwent BAL; BAL fluid was negative for *P. jiroveci* in all four. The remaining five patients received treatment for bacterial pneumonia and responded to therapy. This technique required ultrasonic nebulization in the children, and the youngest patient in this report was 2 years of age.

## Percutaneous Lung Aspiration

The need to obtain lung tissue for a more accurate assessment of the presence of *Pneumocystis* pneumonia has been appreciated for some time. Percutaneous needle aspiration of the lung was already of proven value by the late 1950s in diagnosis of epidemic pneumocystosis in infants [16]. Subsequently, it was successfully employed in infected infants and children with underlying primary and acquired immunodeficiencies [81,150,236,237]. The procedure is performed without general anesthesia so that the child's respiratory function is not further compromised. Under fluoroscopy, a 20-gauge spinal needle with syringe in place is guided into the midportion of the lung. The resultant aspirate (usually less than 0.1 mL in amount) may be transferred directly to slides as unsmeared drops or first cytocentrifuged to increase the concentration of organisms in the sample [238]. Slides are allowed to air dry and then are stained with Gram, Gomori methenamine silver, and toluidine blue O stains. The residual material in the syringe is diluted with 2 mL of sterile saline and cultured for bacteria and fungi.

Children with platelet counts of less than 60,000/mm$^3$ receive fresh whole blood or platelet transfusions before the procedure. Pneumothorax appears to be the major complication encountered. In one series, it occurred in 37% of the patients, and evacuation of air by thoracotomy tube was required in 14% [237].

## Lung Biopsy

It has been argued that aspiration is inferior to biopsy in that the former does not permit histologic examination of lung tissue. Open lung biopsy has been proposed as the most reliable method for identifying and estimating the extent of *Pneumocystis* infection, and for demonstrating the presence of complicating pathologic conditions such as coexistent infection, malignancy, or interstitial fibrosis [144,225,229,239–241]. It may be hazardous, however, to perform a thoracotomy using general anesthesia in patients with marginal pulmonary reserve [242]. Although the procedure has been associated with an acceptably low incidence of serious complications in critically ill children [243–246], determination of its risk-to-benefit ratio based on the infant's underlying disease, expected life span, and clinical condition is appropriate in individual cases [247,248]. Unfortunately, these analyses have not yet been applied rigorously to infants and young children with suspected pneumocystosis. Technical modification in the performance of open biopsy that would avoid general anesthesia and endotracheal intubation (e.g., using thoracoscopy) may be particularly advantageous for diagnosis of *Pneumocystis* pneumonia in small children [249].

Whichever invasive technique is employed for retrieval of tissue to test for the presence of *P. jiroveci*, it is generally agreed that immediate examination and staining of frozen sections or imprints of fresh lung (or alveolar secretions) are critical.* Processing of paraffin-embedded tissue incurs an unnecessary delay of one or more days in diagnosis, and the sections may actually reveal fewer organisms than the imprint smears. Although techniques using Giemsa stain are rapid and specific for the intracystic bodies of *P. jiroveci*, organisms are more readily located and identified against a background of tissue cells with a methenamine silver stain. It should be appreciated that other silver-positive organisms, such as *Torulopsis* [252] and zygomycete spores [253], can mimic the cystic structure of *P. jiroveci* and that smears of *Pneumocystis* rather than fungi should be employed as controls for the stain [254].

Unfortunately, the standard methenamine silver stain technique is slow (3 to 4 hours) and requires expertise usually found only in special histopathology laboratories. To circumvent these problems, several rapid (less than 30 minutes) and simple modifications of the silver stain have been developed [255–258]. Because the results with these stains have not been as consistent as those achieved with the standard, more lengthy procedure, many laboratories have chosen not to use silver for rapid screening of specimens but prefer instead toluidine blue O [33,259–262] and cresyl echt violet [34,263] for this purpose.

*References [16,42,237,239,244,250,251].

## Serologic Tests

It is clear that sensitive and specific serologic methods are desirable to detect active *Pneumocystis* infection. It is disappointing that despite extensive investigation, no method has been proved to be entirely satisfactory.

Serodiagnosis of *P. jiroveci* infection in infants by detection of immunofluorescent antibodies was first reported in 1964 in Europe [264]. It was found that IgM and IgG anti-*Pneumocystis* immunofluorescent antibodies appear sequentially in sera during the course of clinical infection. Both classes of antibodies are present in sera of diseased infants during the first weeks of pneumonia, but only IgG antibodies persist during convalescent periods or in cases of protracted infection [265].

The worth of immunofluorescent antibody tests in the diagnosis of sporadic pneumocystosis was examined subsequently in the United States by Norman and Kagan [266] at the CDC. They observed low rates of serologic reactivity among patients with suspected and confirmed cases, positive results in sera from patients who seemed to have only cytomegalovirus and other fungal infections, and negative results in sera from six infants with primary immunodeficiency diseases and documented pneumocystosis. Although it is possible to increase the specificity and sensitivity of these tests for *Pneumocystis* [267,268], such tests detect background levels of *Pneumocystis* antibody in clinically healthy persons [97,98,268] and, as a result, fail to discriminate between patients with active disease and those who are latently infected with the organism.

The performance of the immunofluorescent antibody test has been hampered for years by the crude *Pneumocystis* antigens employed. Impure antigen results in autofluorescence of uninfected lung tissue, and extensive absorption of sera risks undue reduction in intensity of staining of organisms. For this reason, several laboratories have attempted to prepare a *Pneumocystis* antigen that is isolated as nearly as possible from the lung parenchyma, to which it characteristically clings. Techniques designed to extract free *P. jiroveci* from infected lung include bronchoalveolar saline lavage [30,229], enzymatic digestion of lung homogenates [263], and differential centrifugation of lung homogenates on sucrose [269] or Ficoll-Hypaque density gradients. These purified antigens have been used to generate immune sera that have been applied in immunofluorescent staining of *Pneumocystis* in lung tissue [270,271] and in upper airway secretions [272,273].

To avoid the problem posed by the insensitivity of antibody determinations per se in pneumocystosis, Pifer and colleagues [98] developed a counterimmunoelectrophoretic assay for detecting circulating *Pneumocystis* antigen in suspected cases. In an initial evaluation of the test, antigenemia was demonstrated in up to 95% of children with *Pneumocystis* pneumonia and was absent in normal control children. Antigen also was found in the sera of 15% of oncology patients who did not have pneumonia, however. Thus, although antigenemia appears to be superior to circulating antibody as a serologic correlate of *Pneumocystis* infection, antigenemia alone cannot be equated with a diagnosis of pneumocystosis without corroborating clinical data.

# TREATMENT

## Specific Therapy

Hughes and coworkers [274] in 1974 first demonstrated that the combination of trimethoprim and sulfamethoxazole (TMP-SMX) was effective in treatment of cortisone-induced rat pneumocystosis. This combination was shown to be as efficacious as pentamidine in children infected with *Pneumocystis* who also had underlying malignancy [275]. Several uncontrolled trials of TMP-SMX in congenitally immunodeficient infants [276,277] and in older immunosuppressed children and adults [276,277] confirmed the efficacy and low toxicity of this combination agent. The dosage employed was 20 mg of TMP and 100 mg of SMX per kg of body weight per day, given orally in four divided doses for 14 days. This daily dose was two to three times that used in treatment of bacterial infections. The equivalent efficacy of TMP-SMX and of pentamidine has been confirmed in pediatric cancer patients with *P. jiroveci* pneumonia [278].

TMP-SMX is the drug of choice for treatment of *P. jiroveci* pneumonia in infants and children. The oral route of administration can be used in mild cases, for which the recommended dosage is 20 mg TMP plus 100 mg SMX per kg per day in divided doses every 6 to 8 hours apart. Infants with moderate or severe disease require treatment by the intravenous route with 15 to 20 mg TMP plus 75 to 100 mg SMX per kg per day in divided doses 6 to 8 hours apart. Generally, treatment is given for 3 weeks. Adverse reactions to TMP-SMX will develop in approximately 5% of infants and children without HIV infection and 40% of children with HIV infection; most commonly seen is a maculopapular rash that clears after discontinuation of the drug. Other adverse reactions are uncommon and include neutropenia, anemia, renal dysfunction, and gastrointestinal symptoms or signs.

In infants who do not respond to TMP-SMX or in whom serious adverse reactions develop, pentamidine isethionate in a single daily dose of 4 mg/kg given intravenously may be used. Other drugs have been tested in limited studies in infants and young children with HIV infection and *P. jiroveci* pneumonia, including atovaquone, trimetrexate-leucovorin, oral TMP-dapsone, pyrimethamine-sulfadoxine, clindamycin plus primaquine, and aerosolized pentamidine.

The ease with which TMP-SMX can be administered and its lack of adverse side effects make it an attractive combination for empirical therapy for suspected pneumocystosis. Such treatment is reasonable in infants who are gravely ill and whose outlook for recovery from underlying disease is bleak. Several objections to the universal adoption of this approach have been raised. In at least half of the immunosuppressed children with typical clinical and roentgenographic features of *Pneumocystis* pneumonia, the illness is in fact not related to infection with *P. jiroveci* [279]. Identification of the etiologic agent and proper management of the disorder can be accomplished only by first performing appropriate diagnostic procedures.

Until 1958, no therapy specific for *P. jiroveci* infection was available. In that year, Ivady and Paldy [280] in Hungary recorded the first successful use of several aromatic diamidines, including pentamidine isethionate, in 16 of 19 infected infants. By 1962 the Hungarian investigators had used pentamidine therapy in 212 patients with epidemic *Pneumocystis* pneumonia [189]. During the next several years, favorable responses to this drug were observed in infants and children with both the epidemic and the sporadic forms of the infection [139,144,150]. Treatment produced a dramatic reduction in the mortality rate for the epidemic disease from 50% to less than 4% [278,281]. In the cases of sporadic infection reported to the CDC [110,282,283], survival rates ranged from 42% to 63% for those patients who received the drug for 9 or more days. In cases confined largely to young children and managed at a single institution, cure rates were noted to be as high as 68% to 75% [150,275]. Because spontaneous recovery from *Pneumocystis* pneumonia in immunodepressed persons is rare [284], it is clear that pentamidine therapy reduced the mortality rate in such patients to nearly 25%.

The recommended dose of the drug is 4 mg/kg intravenously once daily for 14 days. Clinical improvement becomes evident 4 to 6 days after initiation of therapy, but radiographic improvement may be delayed for several weeks.

Pentamidine toxicity from intravenous and intramuscular use has been reported. Although toxicity from pentamidine apparently was not a significant problem in the marasmic infants with *Pneumocystis* infection treated during the European epidemics [285], the CDC determined that 189 (47%) of 404 children and adults given the drug for confirmed or suspected *Pneumocystis* infection suffered one or more adverse effects [110]. Immediate systemic reactions, such as hypotension, tachycardia, nausea, vomiting, facial flushing, pruritus, and subjective experience of unpleasant taste in the mouth, were noted particularly after intravenous administration of the drug. Herxheimer's reactions, although described for patients given pentamidine for leishmaniasis [286], occurred rarely [287]. Local reactions at injection sites—namely, pain, erythema, and frank abscess formation—developed in 10% to 20% of patients [110,283]. Elevation in serum glutamic-oxaloacetic transaminase levels was frequently recorded and may have resulted partly from this local trauma. Hypoglycemia ensued not uncommonly after the fifth day of pentamidine therapy but often was asymptomatic [282]. (Hypoglycemia also was observed in pediatric patients with AIDS who were given pentamidine for treatment of *P. jiroveci* pneumonia [288]). Pentamidine-associated pancreatitis also has been reported in children and adults with HIV infection [289–291]. Although overt anemia was rare, megaloblastic bone marrow changes or depressed serum folate levels were noted [282].

## Supportive Care

A critical component in the management of *Pneumocystis* pneumonia is oxygen therapy. Because hypoxemia can be profound, the fraction of inspired oxygen should be adjusted to maintain the arterial oxygen tension at 70 mm Hg or above. The inspired oxygen concentration should not exceed 50% to avoid oxygen toxicity. Assisted or controlled ventilation may be required. Methods of ventilatory support have been a volume-regulated

positive-pressure respirator [292] at either low or high frequency and membrane lung bypass [293]. Other ancillary measures, such as administration of $\gamma$-globulin [144,276,294] to infected congenitally immunodeficient children, warrant further study.

The use of early adjunctive corticosteroid therapy in the treatment of *P. jiroveci* pneumonia in adults with AIDS can increase survival and reduce the risk of respiratory failure [295,296]. A national consensus panel has recommended the use of corticosteroids in adults and adolescents with HIV infection and documented or suspected *P. jiroveci* pneumonia [297]. Two studies have supported the use of corticosteroids in decreasing the morbidity and mortality associated with *P. jiroveci* pneumonia [298,299].

## PROGNOSIS

### Chronic Sequelae

Little is known about the residual effects of successfully treated *Pneumocystis* pneumonia on pulmonary function. Patients may suffer additional "pulmonary" morbidity from other opportunistic infections or from noninfectious complications of underlying disease or its therapy. Robbins and associates [165] were fortunate enough to be able to follow the course of a hypogammaglobulinemic child with *Pneumocystis* infection treated with pentamidine in 1964; during the ensuing 5 years, despite intercurrent episodes of otitis media and bacterial pneumonia, she exhibited normal exercise tolerance and pulmonary function without evidence of reactivation of her *Pneumocystis* infection [242]. Hughes and coworkers [150] evaluated 18 children with underlying malignancies over periods of 1 to 4 years after surviving *Pneumocystis* infection. Although pulmonary function tests were not performed, none of the subjects demonstrated clinical or roentgenographic evidence of residual pulmonary disease. In a subsequent study from the same institution, pulmonary function was assessed serially in surviving children [148]. Significant improvement in function was noted within 1 month of the infection, and all abnormalities resolved by 6 months. This finding is in contrast with the observation of recurrent wheezing episodes and abnormal pulmonary function on follow-up evaluation of infants who had pneumonitis during the first 3 months of life [300,301]. Although later morbidity was independent of the original etiologic agent, 17% of these patients were thought to have *P. jiroveci* infection.

It seems inevitable that respiratory dysfunction can result from severe episodes of *Pneumocystis* pneumonia that provoke interstitial fibrosis or extensive calcification (as discussed earlier under "Pathology"). Cor pulmonale has been observed in infants with such protracted infection [144]. In one notably well-studied patient, an adult with biopsy-proven fibrosis that appeared 4 months after curative pentamidine therapy, serial tests of pulmonary function revealed persistent ventilatory defects of the restrictive type and impairment of carbon monoxide-diffusing capacity [167]. Although a possible link between pentamidine therapy per se and lung fibrosis was suggested by earlier observations in rat pneumocystosis [175,302], healthy animals given the drug exhibit no histologic abnormalities [150]. Moreover, pulmonary fibrosis has been described after *Pneumocystis* pneumonia in patients who received treatment with pyrimethamine and sulfonamide [169] and TMP-SMX [303].

### Recurrent Infection

Recurrence of *Pneumocystis* pneumonia after apparently curative courses of therapy has been documented in infants and children with underlying congenital immunodeficiency or malignancy. As early as 1966, Patterson and colleagues [304] reported the case of an infant with probable severe combined immunodeficiency who experienced one presumptive and two substantiated bouts of pneumocystosis at approximately 5-month intervals; treatment with pentamidine resulted in "cure" on each occasion, although radiographic abnormalities persisted [305]. A few years later, Richman and associates [306] and then Saulsbury [294] described recurrent pneumocystosis in two children with hypogammaglobulinemia; in the first case, three proven attacks responded to pentamidine; and in the second child, two separate episodes of infection were treated successfully with TMP-SMX. At St. Jude Children's Research Hospital, a study of 28 children with malignancy whose pneumocystosis was treated with pentamidine revealed that 4 (14%) suffered a second infection [150,168]. The clinical manifestations, roentgenographic findings, and response to therapy were similar for each child in both infectious episodes. In addition, no differences in host factors were discernible in those patients who had recurrent infection and those who did not. Other examples of recurrent pneumocystosis emerging rather soon after clinical recovery have been observed in patients given either pentamidine or TMP-SMX [307]. Whether recurrences of *Pneumocystis* pneumonia result from reinfection or from relapse of previously treated infection is not known.

Clinical and morphologic studies provide conflicting views on the completeness of *Pneumocystis* killing by specific drugs. The Hungarian workers, who first used pentamidine in epidemic pneumocystosis among infants, witnessed progressive degeneration of *P. jiroveci* in tracheal mucus from the sixth day of therapy; by the tenth day, the organisms had almost entirely disintegrated [186]. In their review of sporadic pneumocystosis in the United States, Western and associates [282] similarly concluded that pentamidine probably eliminates organisms from the lung. In two patients, no microscopically visible *P. jiroveci* organisms were present at 5 and 14 days, respectively, after initiation of therapy. Also, none of 11 patients who died more than 20 days after receiving pentamidine had demonstrable organisms in their lungs, even though they survived an average of 189.5 days after administration of the drug. In ultrastructural studies, Campbell [43] detected what he believed to be the destructive effects of pentamidine on the organisms. In a lung biopsy specimen obtained surgically 16 hours after onset of therapy, structurally normal trophozoites or mature cysts with intracystic bodies were absent. A few apparent "ghosts" of trophozoites were noted within phagosomes of intra-alveolar macrophages.

By contrast, pentamidine does not promptly eradicate potentially viable forms of the organism. Hughes and coworkers [150] identified intact *P. jiroveci* in lung aspirates (or autopsy material) 10 to 20 days after institution of drug treatment. Richman and associates [306] demonstrated normal-appearing *Pneumocystis* organisms in a lung aspirate from a clinically cured patient 3 days after completion of his 14-day course of pentamidine. Similarly, Fortuny and colleagues [130] recovered organisms from induced sputa on each of 11 days of pentamidine injections.

TMP-SMX appears to have only a limited and nonlethal effect on organisms. Experiments have shown that short-term treatment with the drug combination ultimately fails to prevent emergence of recrudescent *Pneumocystis* infection. In one study, a therapeutic dosage of TMP-SMX was given prophylactically to children with acute lymphocytic leukemia for a 2-week period beginning 28 days after initiation of antineoplastic treatment [308]. Although the incidence of *Pneumocystis* infection in these children after TMP-SMX was discontinued was not different from that observed in persons who did not receive the drug, the time interval to development of infection was lengthened. Reinfection rather than relapse may have accounted for the late infections, but relapse seems more likely in view of the following results in experimental animals [309]. Immunocompetent rats were given TMP-SMX for as long as 6 weeks and then placed in individual isolator cages to exclude the possibility of acquisition of new organisms from the environmental air. After 12 weeks of immunosuppressive therapy with prednisone, *P. jiroveci* was still found in the lungs of at least 90% of both the animals given TMP-SMX and the control animals, given no treatment. These human and animal data are particularly relevant to the design of prophylactic regimens to prevent *Pneumocystis* infection in humans. They provide a compelling argument for the need to continue prophylaxis for as long as host defenses are considered to be too compromised to keep latent *Pneumocystis* infection in check.

Reactivation of pneumocystosis is not surprising in light of the pathogenesis and pathology of the infection in the immunodeficient subject. Frenkel and colleagues [19] showed clearly in the earliest experimental animal models of *Pneumocystis* pneumonia that anti-*Pneumocystis* therapy alone was not completely curative and that relapse was to be anticipated unless factors provoking the infection (namely, corticosteroid administration) were minimized. Long-term ultrastructural studies of *Pneumocystis* pneumonia in the rat confirmed that even with tapering of corticosteroid and apparent restoration of immune function, focal clusters of *P. jiroveci* are detectable in surviving animals for at least 21 weeks. Furthermore, in humans, drugs might not reach organisms residing within the foci of fibrosis and calcifications formed during especially severe infection [310]. Indeed, Dutz [24] contended that drugs play no therapeutic role in epidemic pneumocystosis once the chronic plasma cellular infiltrate is established. Radiographic resolution is slow, and survival and permanent immunity to reinfection relate not to chemotherapy but to specific anti-*Pneumocystis* immunoglobulin production in the affected infants. Unfortunately, the congenitally immunodeficient or exogenously immunosuppressed child does not possess such normal immune responsiveness and thus is subject to recurrent infection.

## PREVENTION

The first successful attempts to prevent pneumocystosis with drugs were reported in infants with the epidemic form of the infection. In a controlled trial conducted in an Iranian orphanage where the infection was endemic (attack rate of 28%), the biweekly administration of a pyrimethamine and sulfadoxine combination to marasmic infants before the second month of life entirely eradicated *Pneumocystis* pneumonia from the institution [24]. In a children's hospital in Budapest, Hungary, pentamidine given every other day for a total of seven doses to premature infants from the second week of life provided equally effective prophylaxis. During the 6 years of the study, *Pneumocystis* infection did not develop among 536 premature babies who received this treatment, whereas 62 fatal cases were recorded elsewhere in the city [311].

On the basis of promising results in a rat model of infection, TMP-SMX was evaluated in a randomized double-blind controlled trial in children with cancer who were at extremely high risk for *Pneumocystis* pneumonitis [312]. The daily dosage for prophylaxis was 5 mg of TMP plus 20 mg of SMX per kg of body weight, administered orally in two divided doses. Seventeen (21%) of 80 children receiving placebo acquired pneumocystosis, whereas the infection developed in none of 80 patients given TMP-SMX. No adverse effects of TMP-SMX administration were observed, although oral candidiasis was more prevalent among the patients in the treatment group than among the control patients. In a subsequent uncontrolled trial, the prophylactic efficacy of TMP-SMX was confirmed; cases of infection developed only in those children in whom the TMP-SMX was discontinued while they were still receiving anticancer chemotherapy [313]. More recently, a regimen of TMP-SMX prophylaxis given 3 days a week was shown to be as effective as daily administration [314].

The gratifying success of TMP-SMX prophylaxis in prevention of *Pneumocystis* infection has been duplicated in other medical centers caring for children with underlying malignancy [315]. Administration of the drug for the duration of antineoplastic therapy has become standard practice. It would seem prudent to reserve TMP-SMX prophylaxis for persons at relatively high risk for *Pneumocystis* pneumonitis. Congenitally immunodeficient children and infants with AIDS who have had a prior episode of *Pneumocystis* pneumonia would appear to be prime candidates for preventive therapy. The CDC issued a set of guidelines for chemoprophylaxis against *P. jiroveci* pneumonia in children with HIV infection in 1991 [147,315,316] and updated these guidelines in accordance with the most recent epidemiologic surveillance data demonstrating that despite recommendations established for *P. jiroveci* prophylaxis, no substantial decrease in *P. jiroveci* pneumonitis has occurred [317]. The surveillance data indicated that continued cases were the result of failure to identify HIV-infected infants and the poor

sensitivity of CD4 [318] counts to determine infants' risk for development of *P. jiroveci* pneumonitis, rather than because of treatment failures [319]. These updated guidelines recommend promptly identifying infants and children born to HIV-infected women, initiating prophylaxis at 4 to 6 weeks of age for all of these children, and continuing prophylaxis through 12 months of age for HIV-infected children and offer new algorithms based on clinical and immunologic status to continue prophylaxis beyond 12 months of age. Although no chemoprophylactic regimens for *P. jiroveci* pneumonia among HIV-infected children have been approved as labeling indications by the U.S. Food and Drug Administration (FDA), TMP-SMX currently is recommended as the drug of choice in children with HIV infection. This recommendation is based on the known safety profile of TMP-SMX and its efficacy in adults with HIV infection and in children with malignancies. Alternative regimens recommended for HIV-infected children who cannot tolerate TMP-SMX include aerosolized pentamidine in children more than 5 years of age, oral dapsone, and oral atovaquone. One study suggests that TMP-SMX use is associated with a decreased incidence of *P. jiroveci* pneumonitis and an increased incidence of HIV encephalopathy, both as initial AIDS-defining conditions in infants and children [320].

# ASPERGILLOSIS

Invasive aspergillosis is a disease of the immunocompromised host, including the premature infant in the neonatal intensive care unit (NICU). Although aspergillosis is uncommon among neonates, its incidence in this age group appears to have increased during the past 2 decades, coinciding with the increased survival of infants who are increasingly more immature at birth. Rapid progression from either primary cutaneous aspergillosis or pulmonary aspergillosis to dissemination is common in these immature infants. Thus early recognition with appropriate antifungal therapy is critical for an optimal outcome.

Aspergillosis has been reported in infants who range in age from 1 to 7 weeks. In 1955 Zimmerman [321] described a 13-day-old neonate who became febrile in association with formation of a subcutaneous abscess caused by *Staphylococcus*. Despite antimicrobial therapy for the abscess, pneumonia and hepatosplenomegaly subsequently developed, and the infant died at 1 month of age. *Aspergillus sydowii* was isolated from the lung, brain, pericardial, and pleural fluid. Allan and Andersen [322] reported disseminated aspergillosis in an infant who showed the first signs of disease on the second day of life and who died at 18 days of age. At autopsy, *Aspergillus* was identified in the lung, liver, spleen, heart, thyroid, bowel, and skin of this infant; *Aspergillus* fumigatus grew from cultures of the liver, spleen, and bowel. Luke and coworkers [323] reported disseminated aspergillosis in a debilitated infant who died at 7 weeks of age. At autopsy, *A. fumigatus* was isolated from the blood, heart, and kidneys, and the fungus was identified on microscopic examination in the endocardium, brain, and kidneys. Akkoyunlu and Yücell [324] reported a case of aspergillosis in an infant in whom onset of respiratory and central nervous system (CNS) disease occurred at 2 weeks of age. This infant died at 20 days of age with pneumonia and meningitis. *Aspergillus* was cultured from lung and brain tissue obtained at autopsy. The source of infection was thought to be infected grain on the farm where the infant lived. Infection in two of these four infants was considered secondary to prematurity or to antibiotic or corticosteroid therapy [325,326], but predisposing causes for disseminated aspergillosis were not found in the others [327,328]. Thirty-one additional cases of cutaneous or disseminated aspergillosis in infants have been reported [329–350], and only 11 infants survived [331,333,338–342]. The diagnosis seldom was made before death, and in most cases, the infant died despite institution of antifungal therapy. Infants who survived were more likely to have primary cutaneous infection without dissemination. As in previously reported cases, *Aspergillus* infection was secondary to prematurity [328,344,346,348–350], antibiotic therapy [334], or serious underlying disease [330,331,343,345,347].

## THE ORGANISM

The genus *Aspergillus* contains about 900 distinct species [351], but only 8 have been shown to be pathogenic for humans. Identification of species of *Aspergillus* is made on the basis of morphology and structural details of the conidia-producing structures when grown on specialized media. These fungi reproduce by asexual spores or conidia, developing characteristic branching, septate hyphae as they grow. *Aspergillus* species produce a variety of mycotoxins in nonhuman hosts, but none have been identified in isolates from infected adults. Reported virulence factors include production of protease, phospholipases, and hemolysin, each of which may function to promote invasion of damaged skin [352]. Fibrinogen and laminin receptors are present on the conidia of *A. fumigatus*, and they may augment infection of traumatized skin by interaction with exposed extracellular matrix ligands [353,354]. The species that are pathogenic in humans and animals are *A. fumigatus* (which is the most common), *Aspergillus flavus*, *Aspergillus nidulans*, *Aspergillus niger*, and *Aspergillus terreus*, and less frequently, *Aspergillus glaucus*, *Aspergillus restrictus*, *Aspergillus versicolor*, and *A. sydowii* [352]. Most cases of neonatal aspergillosis are caused by *A. fumigatus*.

## EPIDEMIOLOGY AND TRANSMISSION

*Aspergillus* species are ubiquitous and abundant in the environment. These fungi are found throughout the world in grains and decaying vegetation, soil, and other organic matter. Infection with *Aspergillus* is common in animals [355]. *Aspergillus* spores frequently are isolated from the air because they are easily dispersed, lightweight, and resistant to destruction. Although it has been reported that infection is more common in persons exposed to large numbers of conidia [356–360], occupational predisposition has been questioned [361–365], and a history of inordinate exposure is infrequent. No racial or gender predisposition has been found in the infection rate, but clinical disease in adults is more common in men than in women [366].

Species of *Aspergillus* most often are acquired by humans through inhalation of spores into the respiratory tract, but saprophytic infection with *Aspergillus* may be found in the external auditory canal, skin, nails, nasal sinuses, and vagina [367–370]. Although infection in newborns may result from inhalation of conidia from the environment, the fungus also can be acquired, albeit rarely, during gestation or at the time of birth from an infection in the mother. None of the mothers in one study showed evidence of disseminated infection during pregnancy, and studies of vaginal flora were performed in only one [322]. In the infant of that mother, onset of infection was at 2 days of age; studies were not performed in the mother until 1 month postpartum. Results of culture of vaginal secretions for *Aspergillus* were negative, and appearance by chest roentgenogram was normal. Although person-to-person transmission has not been reported, another source of infection suggested by Allan and Andersen [322] was a second infant in the same nursery. That infant died, but because an autopsy was not performed, the diagnosis of *Aspergillus* infection could not be confirmed.

*Aspergillus* species are found in the hospital setting; thus it is not surprising that infants in the NICU are exposed to this fungus, and that invasive disease results because of the immaturity of their immune system and skin barriers. Sources within the hospital include packaged gauze, tape, limb boards, adhesive monitor leads, and pulse oximetry probes [322,323,371]. Contaminated hyperalimentation fluid has been associated with neonatal aspergillosis. Hospital outbreaks have been associated with airborne contamination during hospital renovation or nearby road construction and from bird droppings in the air ducts [372,373]. Hospital water systems harboring fungi have resulted in airborne transmission from sinks and restrooms. The most common mode of transmission in the neonate is contamination of skin breakdown sites, abrasions, or open wounds [374]. The skin of the premature infant is extremely fragile, does not provide an adequate barrier to the environment, and is prone to breakdown or abrasion even with usual handling.

## PATHOGENESIS

Four morphologic forms of the fungus representing stages of development from germination of conidia to fructification have been identified in humans infected with *Aspergillus* [375]. The progressive changes in morphology may reflect the host's susceptibility or resistance to the fungus. After inhalation, ingestion, or inoculation of the spore, primary hyphae form from the germinating conidia, evoking an intense polymorphonuclear leukocyte response. As infection continues, unbranched, straight, or spiraling hyphae may be seen. Later, characteristic branching occurs, and vegetative forms of *Aspergillus* may be identified in devitalized tissue. In infants, the most common microscopic findings are acute inflammation, hemorrhagic infarction, and subsequent necrosis, and invasion of tissue by characteristic hyphae. Vegetative forms apparently are not found in infants because the disease progresses so rapidly that death occurs first.

Aspergillosis results when the immunocompromised infant with an appropriate portal of entry is exposed to this fungus, resulting in either locally invasive or widely disseminated infection. The primary host defense in humans is the phagocyte, so with inhalation of *Aspergillus* spores, macrophages act by rapidly killing conidia. Neutrophils are involved when conidia escape the reticuloendothelial system and begin the mycelial phase [352]. Oxidative killing is an important host defense [375]. Corticosteroid therapy impairs macrophage and neutrophil killing of *Aspergillus* spores and hyphae [376]. Neutropenia, a common predisposing condition in adults and children with aspergillosis, rarely accompanies neonatal aspergillosis [377,378]. Rather, the underlying problem in neonates appears to be a qualitative defect in neutrophil function [375]. The mechanical disruption of skin by minor trauma, such as removal of adhesive tape securing devices (e.g., intravenous catheters or endotracheal tubes), can allow invasion by *Aspergillus* [379,380].

## PATHOLOGY

Increasingly, *Aspergillus* infection in premature infants in the NICU first manifests as primary cutaneous aspergillosis. In this circumstance, skin biopsy of the lesions reveals extensive disruption of the epidermis, with invasion of the dermis by the septate, 45-degree branching hyphae characteristic of this fungus [341,380]. In infants with aspergillosis, prematurity or antibiotic or corticosteroid therapy may contribute to the risk of infection. In two reported cases of aspergillosis in infants [321,324], however, no predisposing causes were identified. In infants, dissemination of the infection appears to be more common than locally invasive infection [321–324,381].

*Aspergillus* can invade tissue by direct extension, as in orbital or nasal sinus infection into the brain, or it may be widely disseminated by the hematogenous route. In young infants, dissemination appears to result from the primary focus of infection in the lung or skin. The organs most often involved in invasive or disseminated infection are the lung, gastrointestinal tract, brain, liver, kidney, thyroid, and heart [382]. Skin and subcutaneous areas, genital tract, and adrenal glands are sometimes involved. One of the infants with primary cutaneous aspergillosis in the reported cases had skin infection also, and at autopsy *Aspergillus* was identified in the spleen [323]. In disseminated aspergillosis, invasion of blood vessels results in infarction and necrosis. Because the fungus invades and occludes the vessels, hemorrhagic necrosis is frequently seen in the lung and gastrointestinal tract in both infants and adults. Microscopic examination of infected tissues reveals extensive involvement, with dichotomous branching of septate hyphae and the presence of conidial heads in air-containing tissues such as the lung [352]. Necrotizing bronchitis with pseudomembrane formation, invasive tracheitis, and necrotizing bronchopneumonia are found by examination of lung tissue from infants [339,377]. Although granulomatous lesions occasionally are seen throughout an infected organ, suppuration with polymorphonuclear leukocytes and abscess formation are more common.

## CLINICAL MANIFESTATIONS

The number of reports of neonatal infection with *Aspergillus* limited to the skin has been increasing [334,336, 338–342,346,349]. Premature infants have a unique

predisposition to primary cutaneous aspergillosis as a result of their poor skin barrier function. Nine infants have been reported, and all survived with medical or surgical treatment, or both. The cutaneous lesions typically begin as multiple erythematous or violaceous papules that rapidly progress to hemorrhagic bullae, followed by the development of purpuric ulcerations and black eschar formation within 24 hours [344,382]. Lesions often begin on the back or other dependent areas and may be mistaken for pressure sores, but they can occur anywhere on the body where trauma has occurred [339,379]. The lesions of primary cutaneous aspergillosis have been mistaken for bullous impetigo and thermal burns from cutaneous $CO_2$ probe placement [378]. New skin lesions in a premature infant that are black or brown in appearance are suspicious for aspergillosis, but other fungi can give this appearance; therefore, biopsy and culture are necessary to establish an early diagnosis.

Most of the infants with disseminated aspergillosis in reported cases had signs of pulmonary infection that were thought to be pneumonia, not pulmonary infarction. One infant had a cutaneous infection that appeared as a maculopapular rash on the second day of life [322]. Skin lesions became scaly and later pustular. In this infant, enlargement of the liver became apparent, and the infant failed to gain weight. The case reported by Luke and associates [323] was characterized by jaundice, hepatosplenomegaly, heart murmur, ascites, and melena. Cerebrospinal fluid in the affected infant contained white blood cells, but further details were not reported. Jaundice and enlargement of liver and spleen were prominent in the case reported by Zimmerman [326], and the infant described by Akkoyunlu and Yücell [324] had pneumonia and meningitis. Liver disease also was dominant in the cases reported by Mangurten and coworkers [328] and Gonzalez-Crussi and colleagues [329]. Widespread dissemination to the large and small bowel, liver, pancreas, peritoneum, and lung was demonstrated in the infant with aspergillosis and leukemia [330].

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnostic considerations in patients with cutaneous aspergillosis include infections due to other fungi, particularly *Candida* and Phycomycetes organisms. In infants with disseminated aspergillosis without skin involvement, diagnosis is difficult. Although *Aspergillus* can be identified by direct microscopic examination or culture of secretions, its presence does not necessarily indicate infection even in the presence of clinical disease. Demonstration of *Aspergillus* by culture or by microscopic examination of tissue obtained by biopsy or from body fluids establishes the diagnosis. *Aspergillus* species grow readily on almost all laboratory media, and characteristic conidiophores usually are present within 48 hours of incubation. Fungal blood and other body fluid cultures yield *Aspergillus* in less than 75% of cases, however [352].

Hematoxylin-eosin, periodic acid-Schiff, Schwartz-Lamkins, and Grocott and Gomori methenamine silver stains can be used to visualize septate hyphae in tissue. Spores and branching septate hyphae measuring 4 μm in diameter may be seen. The presence of conidiospores in tissue is infrequent, but they may be seen in specimens of saprophytic infection. Mycelia of *Aspergillus* may be confused with pseudohyphae of *Candida*, which usually are smaller and have no branching; yeast forms usually are present. Phycomycetes can be distinguished from *Aspergillus* by their large size, irregularity, and absence of septa. The greatest difficulty is encountered in distinguishing *Aspergillus* in tissue from *Penicillium*, which also can cause infection in humans [383]. The hyphae of *Penicillium* are broader and contain fewer septa. Culture of tissue establishes the diagnosis. Potassium hydroxide smear of the contents of a papule or blister may reveal characteristic hyphae, allowing for a rapid presumptive diagnosis until culture results are available [339]. PCR techniques may be useful in detecting *Aspergillus* species in serum, cerebrospinal fluid, or other potentially infected body fluids [384]. The detection of *Aspergillus* antigen can be helpful in diagnosis, but no data on antigenemia are available for infants [383,385]. The use of galactomannan assays has been demonstrated to have acceptable sensitivity and specificity in adults and in some high risk pediatric populations, such as oncology patients, but few data have been reported in neonates and young infants, and these data suggest poor specificity. Additional diagnostic modalities useful for detecting the extent of involvement in neonates with suspected dissemination infection include lumbar puncture; chest radiography; computed tomography of the brain and chest; abdominal ultrasound examination of liver, spleen, and kidneys; and funduscopic examination. Even if CNS involvement is present, the cerebrospinal fluid may not show an inflammatory response.

## THERAPY

Intravenous amphotericin B deoxycholate remains the drug of choice for treatment for all forms of neonatal aspergillosis (Table 34–2) [386,387]. Amphotericin B should be administered at a dose of 1.5 mg/kg of body weight once daily and infused over a 1- to 2-hour period. This drug is very well tolerated in neonates, and infusion-related adverse effects are rare. Although nephrotoxicity is

**TABLE 34–2** Susceptibility of Fungi to Amphotericin B

| Fungus | Very Susceptible | Moderately Susceptible | Resistant |
|---|---|---|---|
| *Aspergillus* species | | + | |
| *Blastomyces dermatitidis* | + | | |
| *Cryptococcus neoformans* | + | | |
| *Coccidioides immitis* | + | | |
| *Malassezia furfur* | | + | |
| Phycomycetes | | | |
| *Fusarium* species | | | + |
| Mucorales | | + | |
| *Scedosporium* species | | | + |

possible, it is quite uncommon in neonates and young infants. The optimal duration of therapy is not known, but courses up to 10 weeks are not uncommon. Lipid-associated preparations of amphotericin B have had limited use in neonates but have been used to successfully treat invasive aspergillosis in older children. Daily doses of 5 mg/kg apparently are well tolerated. No studies suggesting either safety or efficacy for azoles, often used in older patients with primary cutaneous aspergillosis, have been published. One study, however, evaluated itraconazole in a few neonates [388]. Other antifungal agents, such as voriconazole and caspofungin, have not been evaluated in neonates for pharmacokinetics, safety, or efficacy, and these drugs should not be employed [210,211]. Complete surgical resection of infected, necrotic tissue, in conjunction with amphotericin B therapy, is necessary to treat cutaneous aspergillosis, but preterm infants with extensive cutaneous lesions occasionally may not be able to tolerate full excision. Vitrectomy and intravitreous amphotericin B can be considered the preferred treatment for endophthalmitis caused by *Aspergillus* species [387].

## PROGNOSIS

The prognosis for primary cutaneous aspergillosis in infants is poor because of rapid dissemination, and a high mortality rate is reported even with institution of amphotericin B therapy. Nevertheless, a high index of suspicion—coupled with prompt biopsy of a skin lesion and institution of empirical therapy with amphotericin B continued until results of diagnostic tests including culture become available—has allowed a good outcome in some infants [339].

## PREVENTION

Because the risk of death associated with neonatal aspergillosis remains high, attempts to reduce exposure to *Aspergillus* species are of primary importance in preventing this infection. Filtration systems reduce the airborne transmission of *Aspergillus* spores, and rooms equipped with high-efficiency particulate air (HEPA) filters are virtually fungus free. Construction on or near the NICU should be avoided. Excellent skin care, including the judicious use of adhesive tape, monitor probes, and wound dressing material, is indicated for the prevention of skin breakdown with potential exposure to environmental *Aspergillus* species.

# BLASTOMYCOSIS

Infection with *Blastomyces* has been reported in only four newborns [212–214], although .infection with this fungus occurred in 19 women during pregnancy [214,216–221]. In all but three of these nine women, the infection was diagnosed and treated before delivery. The three women who received no treatment had disseminated infection. Two of the infants born to these three mothers were healthy at birth, but one of them died at 3 weeks of age when *Blastomyces* was identified in lung tissue [212]. The second infant presented at 18 days of age with respiratory distress, and infection with *Blastomyces dermatitidis* was diagnosed by lung biopsy. He received amphotericin B but died 3 weeks after initiation of therapy [213]. The third infant was not infected. Two additional pregnancies ended in stillbirths. Infection with *Blastomyces* was not identified in any of the other infants in the reported cases.

## THE ORGANISM

*Blastomyces* is a dimorphic fungus that has a mycelial form at room temperature and a yeast form at 378° C [222]. The mycelial form is found in soil, where it may exist for long periods [223,389,390]. Conidiophores arise at right angles to the hyphae and are believed to be infectious for humans when mycelia are disturbed. When inhaled, the fungus converts to the yeast form, which is multinucleate, containing 8 to 12 nuclei. It has a thick wall and reproduces by single budding with a broad connection to the parent [390].

## EPIDEMIOLOGY AND TRANSMISSION

Blastomycosis is endemic in the Mississippi and Ohio river valleys in the United States and in parts of Canada [391–401]. Sporadic cases have been reported in Central and South America and in Africa [402]. The infection is more common in middle-aged men [391,400,401], particularly those who are employed outdoors in rural areas [401].

*Blastomyces* is acquired by inhalation of contaminated soil, and the lung is the initial focus of infection [403]. Primary cutaneous blastomycosis by direct inoculation of the organism into skin has been reported [403–405]. It has been suggested that human-to-human transmission does not occur, but Craig and colleagues [406] reported probable human-to-human transmission through sexual intercourse. In addition, mother-to-fetus transmission has been suggested.

Pulmonary infection has been identified as the initial site of infection due to *Blastomyces dermatitidis* [403]. In some instances, the pulmonary disease is self-limited and may resolve without therapy [407]. In some instances, however, both progressive pulmonary disease and dissemination can occur. Although no extensive studies in immunocompromised patients have been conducted, both corticosteroid therapy and other immunosuppressive therapy may increase the risk not only of acquisition of the fungus but also dissemination as well [398,408]. It has been suggested by some studies that a relatively immunosuppressed state occurs during pregnancy, which may account for this increased risk of dissemination [402,409,410]. When dissemination occurs, the skin, bones, and genitourinary system are most commonly involved. The CNS, liver, spleen, and lymph nodes are not commonly affected. Cell-mediated immunity appears to decrease the risk of disseminated blastomycosis [411].

## PATHOLOGY

The inflammatory response in the lung consists of proliferation of polymorphonuclear leukocytes followed by formation of noncaseating granuloma with epithelioid and giant cells. Extrapulmonary sites of infection show a

similar histologic pattern, with the exception of the skin, which shows pseudoepitheliomatous hyperplasia and microabscesses.

## CLINICAL MANIFESTATIONS

Acute symptomatic pulmonary infection in children and adults with *Blastomyces* is associated with abrupt onset of chills and fever, myalgias, and arthralgias. Pleuritic pain is common early, and cough is prominent and may become productive of purulent sputum late in the course of the disease. Resolution of symptoms without therapy is common. Pulmonary infection, however, may become chronic and slowly progressive, with chronic cough, hemoptysis, pleuritic chest pain, and weight loss.

When dissemination occurs, skin infections are reported in as many as 80% of adult cases [403,412–415]. These infections are most common on exposed surfaces, and lesions have a verrucous appearance, particularly in the later stages. Abscesses may occur at the periphery of the lesions. In some patients, the skin lesions appear as shallow ulcerations with central granulation tissue that bleeds easily. Other sites of infection include subcutaneous tissue, bone, and joints and the genitourinary system, particularly the epididymis and prostate. CNS infection is uncommon; however, it usually is associated with headache, confusion, and meningismus [416]. Involvement of the liver and spleen is uncommon.

Of nine women with blastomycosis during pregnancy, seven had disseminated infection; in three of the four in whom studies were done, no evidence of placental infection could be found [216–220]. One of these women had received amphotericin B for 35 days before the birth of her infant. *B. dermatitidis* was cultured from the placenta in the fourth woman, and the organism was visualized in both the fetal and the maternal placental tissue [220]. None of their infants, however, were infected. In one woman in whom placental studies were not done, the fungus was isolated from urine, and her infant died at 3 weeks of age with pulmonary blastomycosis [212]. At autopsy, the infant had no evidence of extrapulmonary infection, suggesting that the fungus may have been acquired by aspiration of infected secretions during birth rather than by hematogenous spread in utero. In the other infant, although the original site of infection was the lung, the fungus was found at autopsy in the kidneys as well [213].

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Because of the rarity of neonatal blastomycosis, enumeration of specific signs that may lead to its diagnosis is difficult. As suggested by findings in the four cases reviewed here, and by extrapolated data in infants with other nonopportunistic fungal infections, the diagnosis should be considered in an infant born in an endemic area for *Blastomyces* who has signs of indolent, progressive pulmonary disease and whose chest radiograph demonstrates bilateral nodular densities. In older children and adults, the clinical picture in acute pulmonary infection with *Blastomyces* appears similar to that in acute bacterial, mycoplasmal, and viral infections. Radiographic findings also are nonspecific. Chronic infection can simulate infection with *Mycobacterium tuberculosis* and other fungi, and mass lesions can suggest carcinoma. Few specific signs are associated with extrapulmonary blastomycosis. The skin lesions may be mistaken for squamous cell carcinoma.

Diagnosis of blastomycosis is made by visualization of fungus in culture of secretions or tissue. Serologic studies to determine the presence of complement-fixing antibodies lack sensitivity [392], but results of immunodiffusion tests for precipitating antibody may be positive in as many as 80% of adult cases [417,418]. No data regarding skin test reactivity or serologic studies in infants with blastomycosis have been reported.

## THERAPY

In view of the rarity of this infection and the limited (or lack of) information regarding pharmacokinetics and safety of antifungal drugs other than amphotericin B in neonates, it appears prudent to treat *Blastomyces* infections in infants with amphotericin B deoxycholate, presumably for a minimum of 6 weeks. Itraconazole and fluconazole have been shown to be safe and efficacious in adults and older children.

## PROGNOSIS

Each of the two reported neonates with blastomycosis died [216,217]. In one the diagnosis was not suspected, and in the other the infection progressed despite antifungal therapy.

## PREVENTION

Data that address prevention of blastomycosis in neonates are lacking. In pregnant women who reside in or travel through endemic areas, however, a respiratory illness should suggest this diagnosis. Prompt diagnosis and therapy for pregnant women have been associated with prevention of illness in young infants [216–221].

# COCCIDIOIDOMYCOSIS

Clinically apparent infection with *Coccidioides immitis* in infants in the first month of life has been reported infrequently despite the high incidence of infection in children living in areas where the fungus is endemic [419]. Most affected infants have been born at term, even when transmission was congenital. The first case of coccidioidomycosis in a neonate was reported by Cohen in 1949 [420]. Although the diagnosis was not established until the infant was 15 weeks of age, signs of pulmonary disease were present at 1 week of age. Dactylitis was evident at 2 weeks of age; the infected finger was the site from which the fungus finally was isolated. Coccidioidomycosis has been reported in 11 other infants; each had clinical onset by 10 weeks of age [421–429]. Although pulmonary disease was prominent in each infant, disseminated infection was found at autopsy in all who died. Two of the infants had signs of meningitis [421,422], but the fungus was isolated from cerebrospinal fluid in only one of them [422]. In two additional reported cases, the infants survived. In one the

diagnosis was made by serologic testing [428], and in the other the diagnosis was established when the fungus was identified in tracheal secretions [429].

## THE ORGANISM

*C. immitis* is the only species of *Coccidioides*; it is found below the surface of the soil. *C. immitis* exists in two phases: saprophytic and parasitic. Saprophytic *Coccidioides* exists in a mycelial form in nonliving material, only rarely in tissue [430]. Hyphae have regularly spaced septa with alternating infectious spores and sterile cells. Arthrospores are infectious components of hyphae and are barrel shaped, measuring 2 to 10 μm in width. Spores may be round or ovoid, in which case they are more typically chlamydospores. An annual rainfall of 5 to 20 inches in alkaline soil and a prolonged hot, dry season followed by precipitation favor the formation of spores [431]. Infectious spores become airborne with minimal disturbance during the hot, dry season and may remain infectious for several weeks. Arthrospores, which have been known to be transported on clothes or other inanimate objects containing contaminated dust, may cause infection great distances from endemic areas [432].

The parasitic form of *C. immitis* is the spherule. The spherule forms in tissue from inhaled or inoculated arthrospores. It measures 10 to 80 μm in diameter and contains endospores, which form within the spherule by cleavage of cytoplasm. Mature spherules rupture, liberating a few hundred to several hundred endospores, which subsequently develop into new spherules [430].

## EPIDEMIOLOGY AND TRANSMISSION

*C. immitis* is found in soil 12 to 14 cm below the surface. Sunlight appears to destroy the fungus. *Coccidioides* is endemic in the Western Hemisphere in the San Joaquin Valley and southern counties of California, southern Arizona, New Mexico, and western Texas, and in Mexico, Guatemala, Honduras, Venezuela, Paraguay, Colombia, and Argentina. In endemic areas, naturally occurring infection has been reported in a variety of wild and domestic animals, including cattle [433], sheep [434,435], dogs [436], horses and burros [437], and rodents [438].

Epidemiologic studies have estimated that approximately 10 million persons currently residing in endemic areas have been infected with *C. immitis* [439]. The rate of infection in susceptible persons arriving in an endemic area is 15% to 50% within the first year [440]. After residence in an endemic area for 5 years, 80% of susceptible persons will become infected. In more than 50% of these, infection is asymptomatic and can be demonstrated only by the presence of delayed hypersensitivity to coccidioidin skin test antigen. The incidence of infection is highest in the early summer and remains high until the first rains of winter. The rate of infection also is higher in dry seasons that follow a season of heavy rainfall [441,442].

No racial or gender difference in incidence of primary coccidioidomycosis has been noted. Primary infection is recognized more frequently in women, however, because they are more likely than men to have cutaneous hypersensitivity reactions [443,444]. Considerable racial differences have been reported in the risk of disseminated disease. Mexican Indian men are three times more likely to disseminate the fungus than white men; black men are 14 times more prone to dissemination than white men; and Filipino men are reported to be 175 times more susceptible than white men [439,445,446]. In women, dissemination is more common during pregnancy [447–451]. Before puberty, no gender difference in clinical manifestations or extent of disease is seen.

Studies to determine explanations for increased susceptibility in men, nonwhite races, and pregnant women have not been performed. Patients with lymphomas, leukemia, and diabetes mellitus are reported to have no higher incidence of clinically significant or disseminated coccidioidal infection than in other persons [452], but disseminated infection may be more common in patients with AIDS [453] and in those receiving corticosteroids or immunosuppressive therapy [454].

Coccidioidomycosis in infants has been considered to result from inhalation of arthrospores. Transmission of coccidioidomycosis from mother to infant in utero has been reported by Shafai [437], who described twins born to a woman who died 24 hours post partum with disseminated coccidioidomycosis. Both infants died with widespread disease. Christian and associates [423] described one case in which onset of disease was at 3 weeks of age in an infant living in a nonendemic area. The infant's mother had inactive coccidioidal osteomyelitis but did not have pulmonary or cutaneous disease, suggesting that infection in the infant may have been acquired in utero or at the time of birth. An infant described by Cohen [420] was born to a mother with active coccidioidomycosis during pregnancy; pulmonary disease was evident in the infant at the age of 1 week, again suggesting that the infection may have been acquired in utero. Respiratory symptoms developed at 2 weeks of age in one infant born to a woman who subsequently died of disseminated coccidioidomycosis, but the infant became clinically well after 3 weeks of therapy with intravenous amphotericin B [422]. Bernstein and co-workers [427] reported onset of disease in an infant at 5 days of age, and although no evidence of disease was noted in the mother, disease onset in the infant shortly after birth suggested in utero transmission of the fungus. By contrast, in the several reported cases of disseminated coccidioidomycosis in pregnant women, only three instances of placental infection were noted, with no evidence of infection in any of the infants [455–459].

Human-to-human transmission of *C. immitis* is rare. Even though infectious arthrospores can be found in residual pulmonary cavities and benign pulmonary granulomas in humans [419], secondary cases within families are unusual. Eckmann and coworkers [447] reported six cases of coccidioidomycosis acquired at the bedside of a patient with coccidioidal osteomyelitis whose cast was contaminated with spherule-containing exudate.

## PATHOGENESIS

The respiratory tract is the initial focus of infection by *C. immitis* in most infants and adults. Direct inoculation of fungus into the skin, reported rarely in adults and older children [448], has not been described in neonates.

After arthrospores are inhaled, mature spherules develop in the bronchial mucosa 4 to 7 days later [449,450]. Granulomas form rapidly, involving pulmonary lymphatics and tracheobronchial lymph nodes. In adults with mild disease, a few scattered lesions may be present; however, when pulmonary involvement is extensive, an outpouring of polymorphonuclear leukocytes fill alveoli, and a radiographic appearance of bronchopneumonia is noted. Ulceration of bronchi and bronchioles can occur, with later development of bronchiectasis. Hematogenous dissemination with multiple organ involvement occurs frequently in neonates, and severe CNS infection is a frequent complication.

## PATHOLOGY

The typical histologic appearance of lesions in *Coccidioides* infection is that of a granuloma with epithelioid cells and Langhans' giant cells. Granulomas occur in infants and older patients. In immunocompromised hosts, suppuration can be prominent, but with adequate host response, hyalinization, fibrosis, and calcification occur.

*Coccidioides* can disseminate by blood flow to any organ in the body. The most significant focus of infection after dissemination is the CNS; the brain, meninges, or spinal cord can be involved. Dissemination to the CNS is most common in children and in white males and is the most common cause of death in patients with coccidioidomycosis [428,451]. In cases of meningitis, presence of a thick exudate encasing the brain invariably results in noncommunicating hydrocephalus. Involvement around the base of the brain usually is more extensive than that above the cerebral cortex. On microscopic examination, the meninges are seen to be studded with small granulomas; similar lesions may be present in the underlying brain substance. In the spinal cord, infection may result in compression by the thick, tough inflammatory membrane, with subsequent loss of motor and sensory functions.

Other organs involved when the infection becomes disseminated include the skin, lungs and pleura, spleen, liver, kidneys, heart, genital tract, adrenal glands, and, occasionally, skeletal muscle. In infants, cutaneous infection most often makes its appearance as a papular rash in the diaper area. The gastrointestinal tract is almost always spared in infants, although the peritoneum and bowel serosa frequently are studded with granulomas. In each of three infants who died of disseminated coccidioidomycosis, the lungs and spleen were involved. One infant had infection in the liver, and one had documented meningitis. Skin infection was present in only one infant [355]. One of the surviving infants had pulmonary infection and osteomyelitis [420], and another had pulmonary infection and chorioretinitis [428].

## CLINICAL MANIFESTATIONS

Although primary pulmonary coccidioidal infection is asymptomatic in 60% of older children and adults [452], and only 25% have an illness severe enough to seek medical attention, each of the infected newborns in the reported cases had signs of pulmonary disease. After an incubation period of 10 to 16 days, signs of a mild lower respiratory tract disorder appear, characterized by a dry, nonproductive cough. Findings can include low-grade fever, anorexia, and malaise, and significant respiratory distress. Physical examination of the chest may demonstrate few abnormalities, but roentgenograms typically show evidence of bronchopneumonia or segmental or peribronchial disease in infants. Hilar nodes often are enlarged, and small pleural effusions are common.

Cavitary lesions became apparent in one infant several months after birth and cleared by the age of 30 months [420]. It is in such chronic lesions that the saprophytic form of *Coccidioides* has been demonstrated [430].

In infants, dissemination of infection is frequent, and when dissemination to the CNS occurs, infection in brain and meninges can be overlooked [453]. Signs, which are vague and nonspecific, include anorexia and lethargy. Nuchal rigidity is infrequent. As the infection progresses, other CNS manifestations include confusion, obtundation, coma, and seizures. Papilledema is a late finding.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Granulomatous pulmonary disease caused by *C. immitis* in adults can mimic tuberculosis, Q fever, psittacosis, ornithosis, viral pneumonias, or other fungal infections, particularly histoplasmosis. In infants, pulmonary coccidioidomycosis may appear to be similar to bacterial infection. In patients with coccidioidal meningitis, considerations in the differential diagnosis include tuberculous meningitis, cryptococcosis, histoplasmosis, blastomycosis, candidiasis, and partially treated bacterial meningitis [427]. In coccidioidal meningitis, the cerebrospinal fluid usually is under increased pressure. Pleocytosis with mononuclear cells is characteristic, but in cases discovered early, a preponderance of polymorphonuclear cells may be found. Eosinophils are common in cerebrospinal fluid in patients with coccidioidal meningitis. The cerebrospinal fluid glucose level is decreased, and the protein level may be markedly elevated.

The diagnosis of coccidioidomycosis must be suspected in infants with unexplained pulmonary disease who are born to mothers who reside in endemic areas. In addition, a history of travel to an endemic area or an occupational hazard involving exposure to contaminated dust may be important clues leading to suspicion of coccidioidal infection [454,460,461]. Establishing a diagnosis of coccidioidomycosis in an infant is difficult. Identification of spherules in pus, sputum, or tissue is diagnostic of infection with *C. immitis*. Direct microscopic examination is best performed if the infected material is partially digested with 10% sodium or potassium hydroxide. Specimens treated by alkalinization are unsatisfactory for culture.

Spherules may be easier to identify if equal parts of iodine and Sudan IV are used. Iodine is absorbed into the wall of the spherule, and Sudan IV differentiates fat globules from spherules [462]. Because spherule-like artifacts are commonly found in sputum and pus, however, direct examination may be misleading. Direct microscopic examination of gastric aspirate and cerebrospinal fluid usually is unrewarding, and even results of culture of cerebrospinal fluid in cases of coccidioidal meningitis can be negative [453]. Identification of spherules in tissue

obtained by biopsy or at autopsy is best accomplished with use of Gridley or Gomori methenamine silver stain. Hematoxylin-eosin may be used but often fails to give enough contrast between spherules and host tissue.

*Coccidioides* can be grown on Sabouraud glucose agar; specimens submitted for culture should include sputum, pus from cutaneous lesions, cerebrospinal fluid, and urine. Because the morphology of mycelia is variable, the fungus can be injected into mice for demonstration of characteristic endosporulating spherules. Culture and animal inoculation are time-consuming and dangerous for laboratory personnel; accordingly, most investigational studies employ immunologic and serologic tests for demonstration of infection with *Coccidioides*.

Studies of development of delayed hypersensitivity in adults, with intradermal injections of 0.1 mL of coccidioidin, have demonstrated that positive reactions may occur 3 days to 2 weeks after the onset of symptoms and may persist for years [430]. In adults without erythema nodosum or erythema multiforme, a dilution of 1:100 of skin test antigen has been used. A positive reaction is manifested 24 to 48 hours after injection as induration of 5 mm or more. Cross-reactions may occur with coccidioidin in patients with histoplasmosis, and coccidioidin can evoke an antibody response to yeast-phase *Histoplasma* but not to *Coccidioides*. False-negative reactions can occur in patients with disseminated infection or in those in whom skin testing is performed before development of cellular immune response to the fungus. Cohen and Burnip [458] performed coccidioidin skin tests in newborns in an endemic area. Among 220 infants studied, positive reactions occurred in 2, but neither had evidence of disease. Two infants born to women with coccidioidal meningitis during pregnancy had negative results on skin testing and no clinical or serologic evidence of infection. Thus skin tests are not useful in establishing a diagnosis of coccidioidomycosis in infants.

Precipitin and complement fixation tests for antibodies to *Coccidioides* have been important in the diagnosis of coccidioidomycosis [463,464]. The complement fixation test has been useful in determining the extent of infection and the prognosis [463]. Precipitating antibodies appear to belong to the IgM class of immunoglobulins and are present in 90% of adults within 4 weeks of onset of symptoms [464]. In most instances, precipitins disappear in 4 to 6 weeks [465]. Coccidioidal antibodies demonstrated by complement fixation tests appear more slowly and only in cases of severe infection. Antibody titers of greater than 1:16 may indicate disseminated infection. The presence of complement-fixing antibodies in cerebrospinal fluid is diagnostic of coccidioidal meningitis; however, only 75% of patients with active meningeal infection have demonstrable antibody in cerebrospinal fluid [463].

A test for detection of coccidioidal antibody using an immunodiffusion technique is available and appears to correlate with the complement fixation test [466,467]. Huppert and associates [468] also have described a latex particle agglutination test that measures antibody paralleling precipitin titers. It is recommended that tests for precipitins and complement-fixing antibodies both be employed for best results in diagnosing coccidioidomycosis [468]. Other serologic tests for coccidioidal antibodies include counterimmunoelectrophoresis [469] and radioimmunoassay [470]; however, results of these techniques in neonates have not been reported.

## THERAPY

Coccidioidal infection appears to be less responsive to amphotericin B than other fungal infections and frequently requires prolonged treatment for control. Intravenous amphotericin B deoxycholate at a daily dose of 1 mg/kg of body weight, however, is the drug of choice for the acute treatment of coccidioidomycosis. Because only 5% to 10% of serum levels of amphotericin B is distributed to the CNS, intrathecal administration of amphotericin B also is necessary. The duration of intrathecal amphotericin B therapy may be monitored by coccidioidal complement fixation titer in cerebrospinal fluid. In patients in whom antibodies never develop in cerebrospinal fluid despite coccidioidal meningitis, the duration of therapy is guided by the cerebrospinal fluid findings.

Although amphotericin B has been used in the long-term treatment of adults with CNS disease, no data on use of this drug in young infants have been reported. Prolonged therapy (for more than 1 year) is almost always necessary. In adults and older children, prolonged therapy with itraconazole or fluconazole rather than amphotericin B has been shown to be useful. In patients with CNS disease complicated by noncommunicating hydrocephalus, cerebrospinal fluid shunting may be necessary.

## PROGNOSIS

The mortality rate among infants with coccidioidomycosis is high. With three exceptions, all of the infants in whom coccidioidal infection was identified died, with infection recognized only at autopsy.

## PREVENTION

Although dust control has been shown to reduce the incidence of infection in persons who are transients in endemic areas [442,471], evidence that such control reduces frequency of infection among long-term residents in these areas is limited. In persons at risk for the development of severe or disseminated infection, attempting to control dust may be beneficial. Cohen [420] suggested that in one case, an infant acquired the infection from inhalation of dust blown into the nursery. Use of air conditioning, filters, and respirators in areas where persons are at risk has been encouraged [472]. Masks have been recommended for persons working in heavily contaminated areas [460]. Other investigators have suggested spraying soil with fungicides [473], but such treatment reaches a depth of only 0.6 cm, which allows the fungus to survive below that level. Careful handling of heavily contaminated dressings by hospital personnel is recommended to prevent acquisition of infection. Isolation or segregation of patients with coccidioidomycosis, however, does not appear to be necessary.

Levine and coworkers [474] have employed a vaccine that has been effective in preventing disease in animals, but results in humans as measured by serologic and skin tests have been erratic [440] and have not shown protection from infection [475].

# CRYPTOCOCCOSIS

The occurrence of cryptococcosis in the neonate is rare, with fewer than a dozen cases reported, most before 1990 [476–481]. All but one infant died, and in each case, organisms with the morphologic appearance of *Cryptococcus* were identified by microscopic examination of tissue obtained at autopsy or by culture. The youngest patient in the reported cases of cryptococcal infection was 20 minutes old [476]. This infant, with obvious in utero onset of infection, had hydrocephalus and an enlarged liver and spleen and died at 40 minutes of age. Encapsulated, yeast-like organisms were identified in the brain, liver, and spleen. Neuhauser and Tucker [477], in their description of three infants with cryptococcosis, noted that one had the disease at birth and died at 19 days of age. At autopsy, organisms with the appearance of *Cryptococcus* were identified in the brain, liver, spleen, and bone. Morphologically similar organisms were recovered in specimen cultures from the infant and from the endocervix of the mother. Nassau and Weinberg-Heiruti [478] reported one case of cutaneous and disseminated cryptococcosis in an infant; Heath [479] described a newborn with endophthalmitis associated with widespread cryptococcal infection. Gavai and associates [480] reported the case of the only surviving infant; blood cultures grew *Cryptococcus neoformans*, and amphotericin B therapy was administered.

In adults, the respiratory tract in most instances has been considered to be the primary focus of infection with *Cryptococcus* [473,482–484], but the fungus appears to have a special predilection for the brain and meninges [485,486]. Dissemination of infection to the CNS is common [486] and is more likely to occur in patients whose defenses against infection are compromised by disease or certain therapeutic agents [487–489].

## THE ORGANISM

The genus *Cryptococcus* is limited to spherical or oval encapsulated cells that reproduce by multilateral budding. Yeast cells vary in size, but most measure 5 to 10 μm in diameter exclusive of the mucinous capsule, which may be one half to five times the size of the cell. Although *Cryptococcus* usually appears on microscopic examination as encapsulated yeast, some strains of *C. neoformans* may produce true hyphae [490]. Of the seven species of *Cryptococcus*, only *C. neoformans* is pathogenic for humans, and it also is the only species that produces hyphae. A saprophytic species, *C. neoformans* var. innocuous, is culturally and morphologically identical to *C. neoformans* and frequently is confused with it.

Three serologic types of *C. neoformans* have been identified using type-specific capsular polysaccharide antisera [491]. Cross-reactions have been noted with *C. albicans*, *Trichophyton* extract, and other antigens [492].

## EPIDEMIOLOGY AND TRANSMISSION

*C. neoformans* has been isolated from all areas of the world. The original isolate was made by San Felice from peaches [493], and Klein [494] recovered the fungus from cow's milk. Emmons [495] isolated *C. neoformans* from soil and later reported that the milk probably had been contaminated with soil that contained excreta from pigeons [496]. Although natural cryptococcal infection in pigeons has not been demonstrated, many authors have suggested that pigeons may be the primary source of pathogenic *Cryptococcus* [497–499]. Others believe the soil to be the primary source, with pigeon excreta merely enhancing growth of *Cryptococcus* [500,501].

Some authors have reported recovery of *C. neoformans* from areas inhabited by birds other than pigeons [502–504], but Fragner [505] was able to isolate *C. neoformans* only from pigeon roosts and nonpathogenic species from roosts of other birds. Nevertheless, it is generally accepted that avian habitats, particularly of feral pigeons, represent the major source of *C. neoformans* for humans and animals.

Sources of *C. neoformans* other than pigeon roosts have been reported. Clarke and colleagues [506] isolated the fungus from apples, and McDonough and associates [507] recovered the organism from wood. Cryptococcus also has been found occasionally in soil not contaminated with bird excreta [508]. *C. neoformans* may cause disease in animals [509], and epidemics of cryptococcal mastitis have occurred in dairy cows [510,511]. None of the personnel caring for the cows acquired the infection.

Human cryptococcosis can occur at any age, but approximately 60% of patients are between the ages of 30 and 50 years [512]. Infection is three times more common in men than in women and is particularly frequent in white men. It has been suggested that this gender difference is related at least in part to the enhanced phagocytic activity of leukocytes for *Cryptococcus* in the presence of estrogen [513].

Infection with *C. neoformans* has been thought to result primarily from inhalation of the fungus from an exogenous source, and the respiratory tract is the primary focus of infection [514]. Direct inoculation into the skin and ingestion of the fungus, however, have been suggested as alternative routes of infection [515–517]. Tonsils also have been reported as a possible initial focus of infection [518]. Littman and Zimmerman [484] along with other investigators have suggested that *Cryptococcus* can be isolated from the oropharynx, normal skin, vagina, and intestinal tract of humans with no apparent disease [519]. Whether isolates are actually *C. neoformans* has been questioned. Tynes and coworkers [520] suggested that pathogenic *Cryptococcus* can be present in sputum as a saprophyte, although before their report, isolation of *C. neoformans* from humans had been considered indicative of disease.

Only one of the mothers giving birth to infected offspring [476–479,481] had any illness during pregnancy that could be attributed to infection with *Cryptococcus* [476–479], and although inhalation of *Cryptococcus* cannot be excluded in newborns infected with this organism, the onset of disease at birth suggests that the transmission of the fungus occurred in utero. Isolation of encapsulated yeast from the endocervix of the mother of one affected infant [477] suggested that transmission in this case may have occurred from an ascending vaginal infection. In no other reported instance of cryptococcal infection during pregnancy has transmission to the infant occurred [519,521]. Kida and colleagues [522] reported the case of a woman with HIV infection and AIDS who died with

disseminated cryptococcal infection 2 days after the birth of her infant, who was uninfected.

Transmission from person to person, except for isolated cases of possible congenital transmission, has not been reported.

## PATHOGENESIS

The presence of pathogenic *Cryptococcus* in humans has been considered to be an indication of disease related to that fungus. The possibility of saprophytic colonization of the skin, sputum, mucous membranes, and feces of healthy persons with *C. neoformans* has been suggested, however [493,523,524]; such colonization would indicate an endogenous source of the fungus. The isolation of encapsulated yeast from the endocervix of an asymptomatic, apparently healthy mother lends support to this contention. Although clinically apparent infection with *C. neoformans* can occur in the normal host, a high incidence of infection has been reported in patients with Hodgkin disease, lymphosarcoma, leukemia, and diabetes mellitus [487–489,524–526], and in those with HIV infection and AIDS. The use of corticosteroids or other immunosuppressive therapy has been associated with a higher incidence of cryptococcosis [527]. Mechanisms of enhanced susceptibility in patients with these underlying disorders or associated with such treatments are similar to those discussed earlier in connection with candidiasis. Cryptococcal infections in these patients, however, have not increased as strikingly as some of the other opportunistic fungal infections [528].

No data specific to infants are available regarding increased susceptibility or resistance to infection with *Cryptococcus*. In the review by Siewers and Cramblett [529] of cryptococcal infections in children, only one of four patients showed evidence of underlying disease. Although gestational age was unknown in two of the eight infants with neonatal cryptococcosis, five of these were born prematurely. Only the surviving infant received antibiotics, and none received corticosteroids. The surviving infant also was receiving hyperalimentation through a central venous catheter.

Presence of a factor in normal human serum that inhibits growth of *C. neoformans* has been demonstrated and may explain the low incidence of clinically apparent cryptococcal infections [530–532]. Alterations in this factor due to disease or therapy may account for the high incidence of cryptococcal infection in patients with diseases of the reticuloendothelial system and in those who are receiving treatment with immunosuppressive drugs. No data are available regarding inhibitory factors in the serum of newborns.

## PATHOLOGY

In infants and adults, the respiratory tract appears to be the primary focus of infection, and follows inhalation of the fungus. In some instances, the skin (by direct inoculation) or the gastrointestinal tract (by ingestion) may be the initial route of infection. In adults, respiratory infection usually is subacute or chronic, and the lesion most commonly encountered is a solitary nodule measuring 2 to 7 cm in diameter and located at the periphery of the lung, at the hilar area, or in the middle of a lobe [484]. Hilar lymphadenopathy usually is minimal. In infants and occasionally in adults, diffuse infiltration [533] or miliary disease similar to that typical of tuberculosis may be evident in the lung [534]. Fibrosis and calcification are rare, but cavitary disease may be found in 10% of adults with pulmonary cryptococcal infection [512]. Small subpleural nodules frequently are found at autopsy in these patients [535], but pleuritic reaction is rare.

Microscopically, pulmonary lesions of cryptococcal infection may give the appearance of nonspecific granulomas. If tissue reaction is minimal, the mass has a mucoid appearance—a finding more common in infants. In most instances, an aggregate of encapsulated budding cells with intertwining loose connective tissue can be seen. Granulomatous reaction may occur, with infiltration of lymphocytes and epithelioid cells but without caseation necrosis. Diffuse pneumonic infiltration seen in infants is characterized by accumulation of fungus in alveoli, and an outpouring of histiocytes and tissue macrophages with ingested organisms may be seen.

Cutaneous cryptococcal infection occurs in about 15% of adult cases [536] but has not been reported in infants. Dissemination can occur through the bloodstream to any organ in the body, including the liver, spleen, kidneys, adrenal glands, bone, and eyes, but the CNS is the most common site of infection after dissemination. Lesions outside the CNS in both adults and infants may appear densely granulomatous, similar to tuberculous lesions [483]. CNS evidence of meningitis includes a gray adherent exudate in the subarachnoid space. More extensive involvement can be present around the base of the brain in older patients. In some instances, small granulomas are present in the meninges and along the blood vessels. The underlying surface of the brain can show small, cystlike lesions consisting of fungal or mucinous material. The cellular reaction can be minimal or extensive, with mononuclear inflammatory cells. The infection can extend along the vessels into the brain substance to a variable depth, resulting in pinpoint cysts in gray matter. Parenchymatous lesions may result from embolization and are found in periventricular gray matter and basal ganglia and in white matter of the cerebral hemispheres. Such lesions are found more often in adults than in infants and appear as nonspecific granulomas or as cysts containing mucinous material from capsules of cryptococci. On occasion, discrete granulomas can be found in any part of the brain, spinal cord, or meninges and may act like space-occupying lesions.

## CLINICAL MANIFESTATIONS

Infants with cryptococcosis have multisystem involvement characterized by enlargement of the liver or spleen or both, jaundice, hydrocephalus, and, in many instances, chorioretinitis. Roentgenologically, Neuhauser and Tucker [477] found intracranial calcifications scattered over the cortex and within the brain substance in three newborns. It is noteworthy that these findings are compatible with those found in many congenital infections, including toxoplasmosis, rubella, syphilis, and cytomegalovirus infection.

One infant was thought to have had toxoplasmosis and cryptococcal infection [477].

Dissemination of *Cryptococcus* to other organs in infants usually produces signs of disease in one or more sites, most commonly the CNS. Signs vary with the location and extent of CNS involvement. Cryptococcal granulomas in the brain may produce signs similar to those of space-occupying lesions caused by other diseases. Meningitis most often manifests as headache, which can become progressively worse, and is accompanied by nausea, vomiting, and lethargy. As infection continues, seizures can occur. On examination, papilledema may be noted, but nuchal rigidity is uncommon. When the brain is extensively involved, obtundation and coma often result. Cranial nerves can be involved, and amblyopia, diplopia, and optic atrophy are frequent findings. The infant who survived had no evidence of cryptococcosis beyond positive blood cultures. No meningitis, ophthalmic, or pulmonary involvement was present.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Neonatal cryptococcal infection can appear similar to congenital infection with *Toxoplasma gondii*, rubella virus, cytomegalovirus, and *Toxoplasma pallidum*. Pulmonary cryptococcal infection can be confused with congenital or neonatal tuberculosis or infections with fungi other than *Cryptococcus*.

CNS infection in infants can be confused with tuberculous meningitis. In cases of localized granulomatous disease, considerations in the differential diagnosis must include brain abscess caused by bacteria, cerebrovascular thromboses, and hemorrhage.

Diagnosis of infection with *Cryptococcus* is made by visualization of encapsulated yeasts in sputum or in cerebrospinal fluid, by culture, or by animal inoculation. Microscopic examinations of pus, sputum, exudates, and cerebrospinal fluid are best performed by using India ink, which is displaced by the capsule. Thick specimens of sputum or pus can be mixed with an equal volume of 10% sodium or potassium hydroxide to dissolve tissue and cellular debris before addition of fresh India ink.

In cryptococcal meningitis, the cerebrospinal fluid usually is under increased pressure, and pleocytosis may be present, with a predominance of mononuclear cells. The cerebrospinal fluid glucose level is decreased in only 55% of adult cases, and protein content is increased in 90% [477]. Direct microscopic examination of cerebrospinal fluid using an equal volume of India ink may show encapsulated yeasts in 50% of culture-proven cases. If yeast is found, the diagnosis is established because *Cryptococcus* is the only encapsulated yeast that infects the CNS in humans.

Specimens submitted for culture when diagnosis of cryptococcal infection is suspected should include sputum, cerebrospinal fluid, blood, urine, and bone marrow. If cutaneous lesions are present, pus also should be submitted.

Microscopic examination of tissue obtained by biopsy or at autopsy may strongly support the diagnosis of cryptococcal infection. Although Gridley and methenamine silver stains demonstrate the fungus very well, other fungi also are visualized with these stains. Specific stains for capsular mucin such as mucicarmine [537] and the Rinehart-Abdul-Haj technique for detection of acid mucopolysaccharide [538] are beneficial, especially for distinguishing *Cryptococcus* from *Histoplasma*.

Immunologic and serologic tests have been proposed as aids in diagnosing infection with *Cryptococcus*. Delayed hypersensitivity to cryptococcal antigens has been noted in adults, but dermal response has not been useful as a diagnostic test [539]. No studies of response to cryptococcal skin test antigens in infants have been reported.

Serum agglutinins, complement-fixing hemagglutination, and indirect fluorescent methods have been described [483,540–545]. Latex and complement fixation tests for detection of cryptococcal antigen in serum and body fluids also have been reported [546–550]. Circulating cryptococcal antigen has been demonstrated in serum and cerebrospinal fluid in patients with meningeal and disseminated infections [551–554]; titers of antigen decrease with recovery. It also has been noted that cryptococcal antibody in serum can increase during recovery from infection with *Cryptococcus*. The latex particle agglutination test has proved to be valuable for detection of cryptococcal antigen in the cerebrospinal fluid of patients in whom findings on culture and microscopic examination of cerebrospinal fluid are negative [552,553,555–557]. No data are available on serologic studies in newborns with cryptococcal infection.

## THERAPY

The drugs of choice for treatment of cryptococcal meningitis are intravenous amphotericin B and oral flucytosine. The amphotericin B dose is 1 mg/kg given once daily, and the flucytosine dose is 100 to 150 mg/kg divided into four oral doses. This dosage should be continued for 4 to 8 weeks. In adults, the combination is given for 2 weeks and is followed by either fluconazole or itraconazole administered orally, but no data exist on the appropriate dose, route, safety, or efficacy of these two antifungal agents in young infants.

## PROGNOSIS

All of the newborns with cryptococcal infection reported who did not receive treatment died within days to weeks of onset of the disease. One infant survived without apparent sequelae after receiving amphotericin B for 6 weeks.

## PREVENTION

Preventive measures should be directed at elimination of exogenous sources of *Cryptococcus*. A solution containing hydrated lime and sodium hydroxide has been shown to be effective in eradicating cryptococci from contaminated pigeon roosts when sprayed on soil containing the organism [558].

# *MALASSEZIA* INFECTIONS

Redline and Dahms [559] in 1981 provided the first description of systemic infection with *Malassezia* species in a very low birth weight infant who was receiving long-term intravenous hyperalimentation including intralipids. Since that first publication, this infection has been

described in patients of all ages, but preterm neonates receiving intralipid therapy constitute the patient population with the highest incidence of fungemia [560].

## THE ORGANISM

The genus *Malassezia* consists of seven distinct species of yeast sharing common morphologic characteristics, nutritional requirements, and molecular features. All members of the genus cause skin disease in humans, but only *Malassezia furfur*, *Malassezia pachydermatis*, *Malassezia globus*, and *Malassezia sympodialis* are associated with neonatal infections [561–564]. Individual yeast cells are 2.5 to 6.0 μm and round, oval, or cylindrical, depending on the species. Each species demonstrates monopolar budding, whereas in certain species, pseudomycelia also may develop [561]. All *Malassezia* species except *M. pachydermatis* are obligatory lipophiles. This requirement for a source of lipid for growth and development explains the concordance of neonatal systemic disease with the infusion of intravenous lipid emulsions.

## EPIDEMIOLOGY AND TRANSMISSION

*Malassezia* is best known as the fungus responsible for tinea versicolor, a common skin infection among adults [565]. *M. furfur* and *M. pachydermatis* also are responsible for catheter-related bloodstream infections, occurring primarily in neonates or older immunocompromised hosts [565]. *M. sympodialis* and *M. globus* are associated with neonatal pustulosis, also known as neonatal acne [562–564]. Skin colonization with *Malassezia* species is nearly universal among adults, and direct transmission from caregivers to infants is the most common route of acquisition in the neonate [565,566]. These organisms persist on the hands of caregivers, despite appropriate hand hygiene, and on many hospital surfaces [561,567]. *Malassezia* organisms can be recovered from contaminated plastic surfaces for up to 3 months, and this persistence may facilitate nursery transmission [568]. *M. pachydermatis* causes infection in dogs, primarily otitis externa, and nursery outbreaks have been associated with colonization in pets of health care providers [569].

The prevalence of colonization with *Malassezia* species among neonates in the NICU ranges from 30% to 100%, with fully half of the infants in some nurseries colonized by the end of the second week of life [570]. Colonization of catheters is thought to occur secondary to skin colonization or direct nosocomial transmission, as seen with clusters or outbreaks of *Malassezia* infections in an NICU [566,569,571,572]. Catheter-associated infections typically occur in infants older than 7 days of age, with the peak incidence in the third week of life [562,573,574]. Neonatal pustulosis typically develops between 5 days and 3 weeks of age [575,576].

## PATHOGENESIS

The pathogenesis of neonatal *Malassezia* infections requires colonization of the skin, followed either by the development of localized neonatal pustulosis or colonization of an indwelling vascular catheter leading to systemic infection. Factors increasing colonization rates among neonates in the NICU include extreme prematurity (gestational age less than 26 weeks), prolonged time in an isolette, the use of occlusive dressings, and prolonged length of NICU stay [566]. Sebum on the skin, especially that of the face, provides the required source of fat in the case of neonatal pustulosis [561]. Catheter-related infections are always associated with the administration of intravenous lipid emulsions, whether Broviac central intravenous or percutaneously placed Silastic catheters are used [566]. Intravascular catheters used only for hyperalimentation (without intralipids) or medication administration and other types of indwelling catheters do not become infected because the infusate they deliver does not provide the lipid nutritional support necessary for *Malassezia* organisms to proliferate. Intravascular catheters frequently develop thrombi or fibrin sheaths that become adherent to the vascular wall, which then may become infected [564,576,577]. The infected thrombus then serves as a source for ongoing fungemia or dissemination to visceral organs through microembolism [576,578,579]. Persistent fungemia is common with neonatal *Malassezia* infections, yet disseminated disease rarely occurs. Rare cases of meningitis, renal infection, liver abscess, and severe pulmonary or cardiac involvement have been reported [573]. Additional predisposing conditions for the development of neonatal systemic *Malassezia* infections include short-gut syndrome, gastroschisis, necrotizing enterocolitis, and complex congenital heart disease [560,570,580,581]. The need for prolonged parenteral, rather than enteral, nutrition is the common denominator in all of these predisposing conditions. Although less common than infections due to spread of the skin-colonizing organisms, infections due to direct nosocomial transmission of *Malassezia* species are documented [561,582].

## CLINICAL MANIFESTATIONS

In neonatal pustulosis, or neonatal acne, the classic lesions are pinpoint erythematous papules that develop into overt pustules, most commonly seen over the chin, cheeks, and forehead, with occasional extension to the neck or scalp [570,580]. Lesions are not irritating to the infant, do not disseminate, and typically resolve over time without therapy—yet the appearance of neonatal pustulosis often is disturbing to parents.

Infants with catheter-related *Malassezia* fungemia typically have any combination of the following nonspecific findings: lethargy, poor feeding, temperature instability, hepatosplenomegaly, hemodynamic instability, and worsening or new respiratory distress [565]. Fever occurs in 53% of cases, and thrombocytopenia, which may be severe, is observed in 48% of cases. Most infants do not become critically ill but have the clinical picture of an ongoing indolent infection. Infants also may have a malfunctioning catheter following occlusion by a *Malassezia*-infected thrombus [561].

## DIAGNOSIS

The diagnosis frequently is made by noting the appearance of a fluffy white precipitate visible in the clear connecting tubing of the infected catheter [578,583,584]. Gram stain of this material reveals the characteristic appearance of *M. furfur* or *M. pachydermatis*, and culture of this material will allow isolation of the organism.

In the absence of any sign of catheter infection, results of culture of blood drawn directly from the catheter may be positive, whereas those obtained from peripheral vessels will be sterile. When *Malassezia* infection is suspected, the laboratory should be notified because these yeasts are not recovered from routine culture media, and special lipid supplementation is required for their growth and identification [583]. Newer methods of fungal identification including PCR techniques may be advantageous in diagnosing this organism but are not yet universally available [585]. Echocardiography is indicated in infants who have persistent fungemia, so that an infected thrombus on the catheter tip can be excluded [586].

### THERAPY

Prompt removal of the infected catheter is the optimal treatment for neonatal *Malassezia* infections. Although dissemination is rare, antifungal therapy usually is provided to ensure clearance of the organism from the bloodstream. Amphotericin B is the most frequently used agent, although in vitro testing suggests only moderate susceptibility of *Malassezia* species to this agent [580]. With removal of the catheter, and thereby the high concentration of lipid, the organism will no longer survive. Vascular catheter complications, including retained catheters and catheter breakage, have been reported with *Malassezia* infections, with one series suggesting *M. furfur* contributes directly to catheter fragility and breakage [587]. Thrombolytic therapy with urokinase and tissue plasminogen activator has been used to facilitate the removal of adherent *M. furfur*-infected catheters and avoid surgical extraction [578,583]. If a large thrombus remains after catheter removal, serial monitoring for dissolution by echocardiography is indicated, and some authorities believe that antifungal therapy should be continued until complete resolution is achieved, although this approach is controversial [584]. Although therapy usually is not indicated with neonatal pustulosis, severe, extensive involvement has been treated with topical ketoconazole ointment [580].

### PROGNOSIS

Prognosis generally is excellent with prompt diagnosis and removal of the infected catheter. Rarely reported complications include severe CNS, pulmonary, and liver disease, with only an occasional death in the extremely low birth weight preterm infant [565].

### PREVENTION

The prevention of *Malassezia* infections in neonates has not been studied. The judicious use of intralipids may significantly limit the risk. In patients in whom intralipid therapy cannot be avoided, this fungal infection should be suspected if the central venous catheter malfunctions or if mild, nonspecific signs of infection are noted.

## PHYCOMYCOSIS

Infection with Phycomycetes organisms occurs infrequently in newborns, but 24 cases have been reported in the literature [588–607]. Sixteen of the infants died; in eight of these, the diagnosis was not suspected during life. One infant died 3 days after the diagnosis was established and therapy was initiated. The gastrointestinal tract was the focus of infection in 8 of 18 cases. Two neonates had only CNS infection, and a third had CNS infection and intestinal involvement. In none of these three was clinical evidence of nasopharyngeal or orbital infection documented. One infant described by Miller and coworkers [595] had rhinocerebral infection and survived, and Lewis and colleagues [599] reported a fatal case in which the affected infant had methylmalonic aciduria and rhinocerebral mucormycosis. White and associates [596] described an infant with cellulitis of the abdominal wall who also survived. In a case reported by Ng and Dear [598], the affected infant had multiple abscesses due to *Rhizopus* infection and survived following treatment. Three additional reports have described infants with cutaneous phycomycosis [601–603]. Two of the three died despite medical and surgical therapy. One of the infants who died had progressive infection that involved the gastrointestinal and respiratory tracts [602]. Four infants had cutaneous infections that developed at intravenous catheter sites [604–607].

Although infection with Phycomycetes is common in adults receiving immunosuppressive therapy and in those with neoplastic diseases, particularly hematologic or reticuloendothelial malignancies [608], none of the infants described in these reports received such drugs or had neoplasia. In adults, acidosis resulting from uncontrolled diabetes mellitus or from hepatic or renal failure appears to contribute significantly to infection with Phycomycetes organisms [608–614]. Although none of the infants in the reported cases had diabetes mellitus or hepatic failure, diarrhea was a prominent finding in 6 of 10 infants; however, acidosis as a complication of diarrhea was not commented on in any of the case reports. One patient had renal failure and acidosis [597], and four others were acidotic, including the infant with methylmalonic aciduria [599,601]. Five of the 24 infants were born prematurely, and 1 term neonate had underlying congenital heart disease and had undergone complex cardiac surgery; intensive antimicrobial therapy was given to all but 1 infant. Two infants were receiving nasogastric feedings [592,599], and in one, cellulitis developed beneath a jejunostomy dressing [596]. In another infant, cutaneous infection developed under an abdominal adhesive tape that attached a radiant thermosensor [603].

### THE ORGANISM

Some confusion regarding the taxonomy of Phycomycetes exists in the literature [615]. For purposes of simplicity, we shall consider Phycomycetes as the class and Mucorales as the order of the three most common genera causing phycomycosis—*Mucor*, *Absidia*, and *Rhizopus* [616]. Phycomycosis, however, also includes infection with species of *Mortierella*, *Basidiobolus*, *Hyphomyces*, and *Entomophthora* [615].

Hyphae are best stained by hematoxylin-eosin, for which they have an affinity; methenamine silver stains are inferior for this fungus. Characteristically, hyphae are randomly branched, are rarely septate, and appear empty. The diameter of hyphae is variable even within the length of the same mycelium. Because these fungi are not sufficiently pathogenic for laboratory animals, attempts at isolation by inoculation are not useful as a diagnostic procedure.

## EPIDEMIOLOGY AND TRANSMISSION

Phycomycetes organisms are found throughout the world in soil, in animal manure, and on fruits. Fungi of this class frequently are found in refrigerators and are commonly known as bread molds [617–619]. *Basidiobolus* and *Entomophthora* can be isolated from decaying organic matter. Infection with Phycomycetes has been reported in humans and animals [620].

In infants with phycomycosis, the infection may have been the result either of ingestion of the fungus into the gastrointestinal tract or of inhalation into the nasopharynx or lung after birth, but saprophytic colonization in the vagina of the mothers and intrapartum acquisition cannot be excluded. Little is known regarding the presence of Phycomycetes on the skin, in the feces, or in pharyngeal or vaginal secretions in the absence of clinical disease. Emmons [620] noted that after exposure to Phycomycetes patients with bronchiectasis may cough up spores for several days in the absence of clinical infection. Isolation of these fungi from other sites without evidence of disease has not been reported, but data from newborns suggest that saprophytic colonization with Phycomycetes may be similar to the commensalism with *Candida*. No evidence is available to suggest that human-to-human transmission occurs. In one case reported by Dennis and coworkers [593], *Rhizopus oryzae* was isolated from the Elastoplast that was used as an adhesive for the abdominal dressing. In another infant described by White and coworkers [596], abdominal wall cellulitis developed beneath the adhesive dressing of a jejunostomy. Linder and colleagues [603] isolated *Rhizopus* from the adhesive tape used to attach the thermosensor. In each of these infants, cultures of similar dressings and of tape used in the same units failed to grow the fungi [596,603].

## PATHOGENESIS

The bowel is a frequent site of infection in infants; disease in this location appears to be associated with malnutrition or diarrhea [590,601]. Underlying medical conditions seem to play a major pathogenic role in most cases of phycomycosis. The high incidence of rhinocerebral infection in adults with diabetes mellitus has been noted, but the biochemical abnormality that increases susceptibility is considered to be acidosis, rather than endocrine dysfunction [592,610]. Straatsma and coworkers [608] have suggested that acidosis from any cause, including hepatic or renal failure, may increase susceptibility to phycomycosis. Of interest are the reported infants and adults with gastrointestinal phycomycosis. Most had diarrhea, which may be accompanied by severe acidosis, especially in infants. Whether diarrhea preceded or was a complication of gastrointestinal phycomycosis in these cases cannot be determined. The mechanism of increased susceptibility to infection with Phycomycetes in an acidotic state is incompletely understood. Although optimal growth of Phycomycetes occurs at pH 4.0 in vitro but not at pH 2.7 or 7.3 [621], acidification is not suitable for the sexual cycle of Phycomycetes. In the host, acidosis may delay polymorphonuclear response and limit fibroblastic reaction [610,614]. Prematurity, antibiotics, and diarrhea may have been some of the predisposing factors in the infants who died of this infection.

## PATHOLOGY

The characteristic histopathologic features of infection with this class of fungi include vascular invasion with necrosis or hemorrhage. Necrotic and suppurative lesions demonstrating massive infiltration by polymorphonuclear leukocytes are seen in invasive or disseminated phycomycosis. In patients with subcutaneous infection, lesions usually are granulomatous with epithelioid and Langhans' giant cells. Conspicuous infiltration with eosinophils occurs in subcutaneous infection, particularly with species of *Basidiobolus*. Vascular invasion in such cases is rare.

## CLINICAL MANIFESTATIONS

The clinical manifestations of phycomycosis in neonates and young infants depend on the site or sites of infection. With cutaneous disease, the appearance is similar to that in cutaneous aspergillosis, and involved sites include surgical wounds, intravascular catheter insertion sites, and areas of skin breakdown. The usual symptoms of gastrointestinal phycomycosis in adults are bloody diarrhea and cramping abdominal pain. Because vascular invasion and necrosis occur, perforation and peritonitis with a rapidly fatal course are common. In seven of eight infants with phycomycosis, diarrhea and abdominal distention or signs of peritoneal irritation, or both, were prominent findings. Two infants had free air in the peritoneal cavity from perforation. One infant without abdominal signs had CNS infection without other organ involvement. In extremely premature and low-birth-weight neonates, invasive fungal dermatitis has been reported to be caused by Phycomycetes [622].

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The clinical picture in infants with phycomycosis appears to be very similar to that in children with aspergillosis. Phycomycetes have the same affinity for vascular invasion, hemorrhage, necrosis, and suppuration. Bacterial infection in the lung may be indistinguishable from phycomycosis on clinical grounds. Hemorrhagic infarction of the lung or bowel from other causes has the same presenting signs as those due to infection with Phycomycetes. The cerebrospinal fluid in infants with CNS infection does not show a consistent pattern. Glucose and protein levels often are normal. Xanthochromia with small numbers of red blood cells is common, and a few mononuclear or polymorphonuclear cells may be present [614].

The diagnosis of phycomycosis should be considered in debilitated infants, particularly those with acidosis related to diarrhea, or with hepatic or renal failure, who do not respond to correction of the acidotic state. Sinus or orbital abnormalities in such patients should be investigated for the presence of Phycomycetes. Adults receiving immunosuppressive therapy or antimetabolites for hematologic diseases in whom pulmonary or gastrointestinal symptoms develop must be evaluated for possible Phycomycetes infection.

The diagnosis of infection with these fungi can be difficult because culture results frequently are negative [623]. Demonstration of the fungus is best accomplished by microscopic examination of tissue and visualization of the broad, branching, nonseptate hyphae. A 10% solution of potassium hydroxide is used, although hematoxylin-eosin staining is

preferred for specimens of tissue. Exudates from the nasopharynx or necrotic tissue obtained by débridement should be cultured on Sabouraud glucose agar. Because of the ubiquity of these fungi, demonstration of the organism in tissue is necessary to establish a diagnosis of phycomycosis.

Although normal human serum contains substances that inhibit growth of *Rhizopus* in vitro [624], serologic and immunologic tests have not been extensively studied as diagnostic aids for patients with phycomycosis. Bank and associates [625], using an extract of *Rhizopus* isolated from a patient, produced a cutaneous reaction with an intradermal injection in the patient but not in control subjects. They also found complement-fixing antibodies in the serum of the patient but not in controls, although the same extract was used. Jones and Kaufman [626] demonstrated antibodies to a homogenate of the fungus by an immunodiffusion technique in 8 of 11 patients with mucormycosis.

## THERAPY

Of paramount importance in the treatment of phycomycosis is correction of metabolic derangement; cessation of antibiotics, corticosteroids, or immunosuppressive agents whenever possible; and débridement or excision of necrotic tissue [627–631]. In conjunction with these measures, various antifungal agents in addition to amphotericin B have been employed, but no data are available that allow recommendations for specific drugs, doses, or duration.

## PROGNOSIS

The diagnosis of phycomycosis in infants most often is made at autopsy. The diagnosis was not considered before death in nine patients in the reported cases. In 13 patients, the organism was identified and therapy was given; 6 of the 13 recovered [588–607].

## PREVENTION

Measures to protect the fragile skin of immature extremely low birth weight infants should limit the ability of these fungi to invade. As with *Aspergillus* infection, activities that would allow exposure to Phycomycetes such as construction, should be limited in or near the NICU.

# DERMATOPHYTOSES

The dermatophytes—*Epidermophyton*, *Microsporum*, and *Trichophyton*—often are responsible for infection of keratinized areas of the body, including skin, hair, and nails. Superficial infection with these "ringworm" fungi has been reported infrequently in newborns, although infants have been considered susceptible to infection with these specialized fungi [632]. In 1876 Lynch [633] reported the case of an infant with tinea faciei who was only 6 hours of age. Unfortunately, the diagnosis was made clinically, and no documentation of dermatophyte infection by microscopic examination or culture was obtained. More recently, Jacobs and colleagues [634] described an 8-day-old infant with tinea faciei due to *Microsporum canis*. An outbreak of neonatal ringworm in five infants in an NICU was linked to the index case in a nurse who was infected with *M. canis* by her cat [635]. Dermatophyte infections in infants from a few weeks of age to several months of age have been described [636–648].

Because of the infrequent reports of dermatophyte infections in infants, few investigative studies defining factors contributing to increased infantile susceptibility or resistance to infection by dermatophytes have been performed [642,643]. Wyre and Johnson [644] suggested that increased humidity in the incubator may have contributed to the risk of infection in an infant with pityriasis versicolor, and Lanska and associates [646] indicated that prolonged exposure to humidified oxygen by hood may have increased susceptibility to the cutaneous fungal infection observed in three infants.

## THE ORGANISM

Dermatophytes have been placed in the class of imperfect fungi, Deuteromycetes, in the order Moniliales [616]. Because of a sexual stage in some dermatophytes, however, some authors have preferred to classify certain genera as belonging to the class Ascomycetes [649,650].

Hyphae of dermatophytes are long, undulant, and branching. Many septa are present along the length of hyphae. Hyphae break at the septa into barrel-shaped arthrospores. In culture, dermatophytes form conidiophores, with resulting microconidia and macroconidia. Genera and species identification is based on gross characteristics of colony and microscopic morphology of conidia. A complete review of distinguishing features may be found in standard mycology textbooks [651].

## EPIDEMIOLOGY AND TRANSMISSION

Dermatophytes are distributed throughout the world in humans and animals; many also are found in soil, water, vegetation, and animal excrement [652]. The fungus can contaminate combs, hairbrushes, shoes, and shower floors and has been isolated from air [653,654]. Contamination of soil with dermatophytes has been thought to occur in keratinous debris from infected animals and humans [652], and no evidence is available to suggest that these fungi are free-living saprophytes in soil.

Dermatophyte infection most often is acquired from contact with infected persons or animals. Infections with *Microsporum gypseum* can result from contact with soil contaminated with the fungus. Human-to-human transmission can occur with *Epidermophyton floccosum*, *Microsporum audouinii*, *Trichophyton mentagrophytes*, *Trichophyton rubrum*, *Trichophyton schoenleinii*, *Trichophyton tonsurans*, and *Trichophyton violaceum* [655]. Zoophilic dermatophytes include *M. canis*, *Trichophyton gallinae*, *T. mentagrophytes*, and *Trichophyton verrucosum*. Although *M. canis* usually is transmitted to humans from young animals, particularly kittens, transmission between persons is suggested in the case of an infant reported by Bereston and Robinson [636]. Pinetti and coworkers [656] isolated *M. canis* and *M. gypseum* from flies, which suggests an additional mode of transmission.

In newborns with dermatophyte infection, the fungus probably is acquired after birth from contact with infected nursery personnel, household members, or animals. In the case reported by Lynch [633] of clinically apparent infection at 6 hours of age, the fungal infection probably was

acquired in utero. In this case, evidence of infection in the mother was lacking, but the fungus has been demonstrated on skin in the absence of clinical disease [657,658].

## PATHOGENESIS

Despite worldwide distribution of dermatophytes and frequency of exposure of humans to these fungi, the incidence of clinically apparent infection in infants and adults is considerably lower than would be expected. Few studies defining host factors responsible for protection have been performed. Although Knight [659] has shown in experimental studies in humans that macerated moist skin is more susceptible to the infection than dry skin, the role of immunologic factors in the control of dermatophyte infection remains obscure. Repeated infection may occur at identical sites as long as 2 years after primary infection [659,660], despite reports that infection may offer partial immunity to reinfection [661,662].

Roth and colleagues [336] along with others [663–667] have demonstrated antidermatophyte activity in normal human serum and have suggested that this substance may restrict dermatophyte infection to superficial layers of skin. No studies investigating the role of antifungal activity in sweat have been reported, although immunoglobulins and antibodies have been demonstrated in sweat [668]. Although antidermatophyte activity has been reported in serum at birth [667], no specific studies have been performed in infants to define other host factors or to determine immunologic consequences of dermatophyte infection.

Most infected neonates weigh less than 1000 g at birth and have a gestational age of less than 26 weeks.

## PATHOLOGY

Dermatophyte infection generally is confined to keratinized areas of the body and only rarely invades deeper tissues. Lesions may be vesicular and contain serous fluid. Inflammatory reaction with polymorphonuclear leukocyte infiltration is minimal and usually represents secondary bacterial infection. Occasionally, intense inflammatory reactions may occur in the absence of bacterial infection, especially in children with tinea capitis resulting from *T. mentagrophytes*. These pustular lesions, or kerions, surround infected hair follicles and appear to be reactions to virulent strains of fungus.

Favus is a chronic infection usually caused by *T. schoenleinii* or *T. mentagrophytes*. Granulomatous formation occurs, with giant cells and masses of hyphae around the hair follicle. Overlying the infection is a crust of cellular debris and degenerating hyphae. This lesion is convex, and scarring and alopecia appear after healing.

In infants of extremely low birth weight, invasive dermatitis can occur with *Trichosporon* species. Skin biopsies reveal invasion of the epidermis with this yeast, often with spread along hair follicles and then into the dermis (Fig. 34–5), similar to the histologic picture of invasive fungal dermatitis caused by *Candida* species, *Aspergillus* species, or Phycomycetes organisms [652].

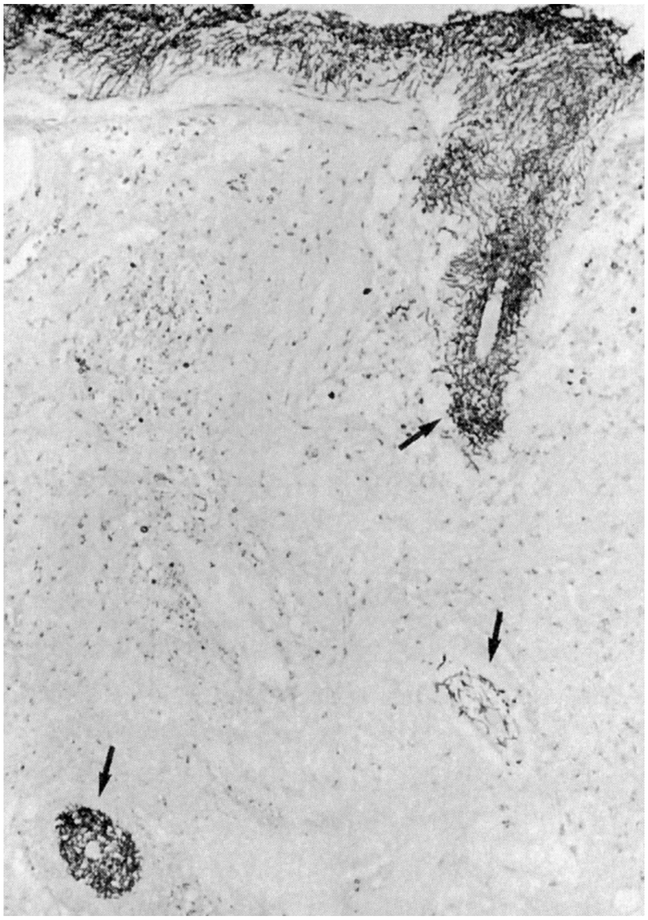

**FIGURE 34–5** Skin biopsy specimen from extremely low birth weight infant with invasive fungal dermatitis caused by *Candida albicans*. Intense involvement of the epidermis with pseudohyphae extending along hair follicles (*arrows*) is demonstrated following staining with Grocott methenamine silver. ×10.

## CLINICAL MANIFESTATIONS

Dermatophytosis is classified generally by focus of infection and less commonly by species of infecting fungus. Tinea capitis is a fungal infection of the scalp and hair caused by *Microsporum* and *Trichophyton*. It occurs most often in infants, older children, and adults. Alteras [663] reported that in a group of 7000 patients, 70 infants between 2 and 12 months of age had tinea capitis. In this study, *M. audouinii* was the most common fungus in infants. Other fungi reportedly causing tinea capitis include *M. canis*, *T. violaceum*, *T. tonsurans*, *T. mentagrophytes*, *T. schoenleinii*, *Microsporum ferrugineum*, *E. floccosum*, and *T. rubrum*. Infection begins with small scaling papules that spread peripherally, forming circular pruritic patches. Both kerion and favus formation can occur.

Tinea corporis, or ringworm of smooth skin, can result from infection with species of *Microsporum*, *Trichophyton*, or *Epidermophyton*, although infections with *Microsporum* species are the most common (Fig. 34–6). Infants and children appear to be more susceptible to tinea corporis than adults. King and coworkers [637] described five infants with tinea corporis who ranged in age from 3 weeks to 7 months. *Microsporum* species predominated in that study, but one infant, who was 8 weeks of age, was infected with *E. floccosum*. In older children, *M. canis* and *T. mentagrophytes* are more common causes of tinea corporis. Lesions, which may be single or multiple, are round or oval scaling, erythematous patches. As infection spreads peripherally, the center of the

**FIGURE 34–6** Tinea corporis caused by *Microsporum* species in a 4-month-old infant.

lesion may show some clearing. In some instances, an intense inflammatory reaction with vesiculation at the margins, accompanied by severe pruritus, may be noted. Patches of infected areas may coalesce, forming extensive plaques with serpiginous borders. Deep granulomas or nodules may form, especially when the infection is caused by *T. rubrum*.

Tinea cruris is a fungal infection of the groin, perineum, or perianal area and most often is caused by *E. floccosum* (Fig. 34–7). *T. mentagrophytes* and *T. rubrum* are unusual causes of infection at these sites. Although *Candida* species account for a majority of fungal infections in the diaper area, King and coworkers [637] described one infant with *E. floccosum* infection in the perineum. Infection with this fungus is characterized by brownish areas of scaly dermatitis with small, superficial pustules at the periphery of the lesion. Infection with *T. mentagrophytes*, which usually spreads from the feet, is associated with marked inflammation. Tinea cruris caused by *T. rubrum* may be unilateral and may be only one part of a generalized scaly, erythematous, plaquelike eruption. Tinea pedis, or athlete's foot, is the most common dermatophyte infection in adults but is rare in infants.

**FIGURE 34–7** Tinea cruris infection with *Epidermophyton floccosum* in a young infant.

In extremely immature premature neonates, invasive fungal dermatitis can occur in areas of skin breakdown (Fig. 34–8) [652].

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Dermatophyte infection may be mistaken for seborrhea, impetigo, or psoriasis. Tinea capitis may appear similar to alopecia areata, but scaling usually is absent in the latter. The presumptive diagnosis is made by direct microscopic examination of infected material. Areas to be examined should be cleansed with 70% alcohol, and scrapings should be made with a scalpel or scissors from the active periphery of the lesion. If vesicles are present, the tops should be removed for examination. Hairs infected with *M. audouinii* or *M. canis* may be identified by using Wood's light, which emits monochromatic ultraviolet rays. Infected hairs show a green-yellow fluorescence and may be removed for examination. Scrapings from nails, obtained from deep layers, should be thin. Specimens are placed on a glass slide, and a few drops of 10% sodium or potassium hydroxide are added. A coverslip is added, and the specimen is gently heated over a low flame. Microscopic examination under low power should take place immediately. The presence of hyphae confirms the diagnosis of fungal infection. Young hyphae appear as long, thin threads, and older hyphae have many spores. Spores may be found either within the hair follicle or around its base. Shelley and Wood [669] have described a technique of crushing the hair. They found it to be superior to the use of potassium hydroxide for identifying the fungus in the hair. Identification of the genus and species of dermatophyte can be made only by culture. Infected material should be cultured on a Sabouraud glucose agar slant, and microscopic examination of hyphae and conidia performed.

In premature infants with brown- or black-appearing lesions at areas of skin trauma, the diagnosis of invasive fungal dermatitis should be determined by skin biopsy and culture (see under "Aspergillosis" and "Phycomycosis"). Blood cultures also may yield *Trichosporon beigelii* if this etiologic agent is responsible for the skin lesions.

## THERAPY

Topical therapy with keratolytic or fungicidal medications may be beneficial in some cases of dermatophyte infection, especially tinea pedis, in which results with use of griseofulvin are not encouraging. Whitfield's ointment, 1% solution of tolnaftate, or an ointment with 3% each of sulfur and salicylic acid may be used. Topical therapy should be continued until culture specimens and scrapings are negative for fungus. For invasive fungal dermatitis in premature infants, amphotericin B deoxycholate administered intravenously is the agent of choice. Some studies, however, have suggested tolerance of *Trichosporon* species to amphotericin, and fluconazole has been shown to be effective in the treatment of trichosporonosis.

## PROGNOSIS

Untreated dermatophyte infection is slowly progressive and can be disfiguring, especially in cases of kerion and favus reactions. Secondary bacterial infections are common, particularly in cases of tinea pedis. Deep tissue

**FIGURE 34–8** Diffuse involvement of the buttocks by invasive fungal dermatitis, caused by *Trichosporon* species, in an extremely low birth weight infant. The lesion is a tightly adherent white-and-buff-colored crust.

invasion occurs in extremely low birth weight neonates, typically with *T. beigelii* infections, and most reported cases have had a fatal outcome [652].

## PREVENTION

Separate combs, hairbrushes, and clippers should be available for the newborn and should not be shared with others in the household. Infected animals and household contacts should be promptly treated [670].

# ANTIFUNGAL THERAPY IN NEONATES AND YOUNG INFANTS

Amphotericin B deoxycholate is the mainstay of therapy for invasive fungal infections in neonates. For certain infections, flucytosine or fluconazole may be useful (Table 34–3). Although newer azoles, lipid formulations of amphotericin B, and echinocandins have been studied and shown to be useful in adults and older children with some invasive fungal infections, limited or no information regarding the pharmacokinetics, safety, and efficacy of these new antifungals in neonates is available. For many invasive infections in adults (e.g., candidiasis, aspergillosis), these agents have been demonstrated to have similar efficacy but reduced toxicity, especially the dose-limiting toxicity often noted with conventional amphotericin B in adults and older children. For some fungal infections, however, amphotericin B has limited in vitro activity, and use of alternative agents may be necessary.

## AMPHOTERICIN B

Amphotericin B is a polyene antimicrobial that reacts with sterols in cell membranes, resulting in cellular damage and lysis. Serum levels in adults average 1.5 μg/mL 1 hour after intravenous injection of 0.6 to 1 mg/kg; the half-life is approximately 24 hours, but levels of 0.14 μg/mL have been detected in serum for at least 3 weeks [671]. Only one tenth to one twentieth of the serum levels is distributed into the cerebrospinal fluid.

Few studies have been performed of the clinical pharmacology of amphotericin B in newborns or older infants from which an accurate recommendation for dosage can be extrapolated. McCoy and coworkers [672] reported peak serum concentrations at 1 hour of 2.6 μg/mL in the

**TABLE 34–3** Antifungal Drugs for Infants with Systemic Fungal Infection

| Agent | Metabolism/Excretion | CSF/Serum Concentration | Dose Change in Renal Failure | Daily Dose (mg/kg) |
|---|---|---|---|---|
| Amphotericin B | | 40–90% | None | 0.5–1.5 |
| Liposomal amphotericin B | Hepatic | ? | None | 3–6 |
| Flucytosine | Renal | >75% | Yes | 100–150 |
| Fluconazole | Renal | >60% | Yes | 2–12 |
| Itraconazole | Hepatic | <1% | None | 2–5 |

CSF, *cerebrospinal fluid.*

mother and in arterial cord blood after a maternal infusion of 0.6 mg of amphotericin B. The amphotericin B concentration in the amniotic fluid was 0.08 μg/mL. Ismail and Lerner [217] reported that levels of amphotericin B in cord blood were 33% of the maternal serum concentrations. Hager and associates [220] obtained simultaneous amphotericin B levels in maternal blood, cord blood, and amniotic fluid 26 hours after an infusion of 20 mg. The levels were 1.9, 1.3, and 0.3 μg/mL, respectively. Ward and coworkers [673] reported that serum levels of amphotericin B in a premature infant were similar to those found in older children and adults, and those levels persisted for at least 17 days after amphotericin B had been discontinued.

The toxicity of amphotericin B in humans can be significant. Adults and older children frequently experience nausea, vomiting, headache, chills, and fever during infusion of this agent [674]. Infusion-related adverse events are rare in neonates, however [675]. Hypokalemia can develop, but often concomitant drugs being administered with amphotericin B to the neonate may account for this association. Serum electrolytes should be carefully monitored, and hypokalemia can be corrected with potassium replacement. Nephrotoxicity is the most important toxic effect in adults and older children. This adverse effect has been shown to correlate with the total dose of amphotericin B [676] and results from drug-induced renal vasoconstriction, and from direct action of amphotericin B on renal tubules [677]. Other findings can include a rise in serum creatinine and blood urea nitrogen levels and a decrease in creatinine clearance, and cylindruria, renal tubular acidosis, tubular necrosis, and nephrocalcinosis. Nephrotoxicity from amphotericin B is rare in neonates; when it occurs, it often is the result of infection rather than an adverse drug effect and is reversible with a reduction in daily dose from 1.0 to 0.5 mg/kg [675,678].

The effect of amphotericin B on the fetus has not been extensively studied. Several reports of the use of amphotericin B in pregnant women have now been published [216–221,522,672,679–685]. In no instance was there evidence of teratogenicity or fetal toxicity related to this antifungal agent. Amphotericin for use during pregnancy is a category B drug. Systemic fungal infections have been successfully treated in pregnant women without obvious effects on the fetus, but the number of cases reported has been small. Adequate and well-controlled studies have not been conducted; therefore, use of this drug during pregnancy is indicated only if it is clearly needed [686].

The initial intravenous dose of amphotericin B in neonates should be 0.5 to 1.0 mg/kg, and the drug should be suspended in sterile water in a concentration of no greater than 0.1 mg/mL. The maximum daily dose and duration of therapy depends on the focus and extent of fungal disease [687], and on the minimal inhibitory concentration (MIC) of amphotericin B for the organism [688]. The neonatal dose is 0.5 to 1.5 mg/kg per day. Although some authors have suggested monitoring serum levels of amphotericin B [689,690], others disagree because of the predictable pharmacokinetics of this drug [691,692]. Rate of administration varies, but typically the dose can be given over 1 to 2 hours, and no longer than 4 hours.

Intrathecal administration of amphotericin B can be necessary in patients with coccidioidomycosis meningitis. Few data are available on the ideal intrathecal dose of amphotericin B in children with fungal meningitis. The initial intrathecal dose in infants should be 0.01 mg, gradually increased over a period of 5 to 7 days to 0.1 mg given every other day or every third day. Amphotericin B for intrathecal administration should not exceed a concentration of 0.25 mg/mL of diluent, and further dilution with cerebrospinal fluid is recommended. Complications of intrathecal amphotericin B administration include cerebrospinal fluid pleocytosis (arachnoiditis), transient radiculitis, and sensory loss.

Three lipid formulations of amphotericin B are commercially available: amphotericin B lipid complex (ABLC), amphotericin B cholesteryl sulfate complex (i.e., amphotericin B colloidal dispersion [ABCD]), and liposomal amphotericin B (L-AmB). These formulations differ in the amount of amphotericin B and lipids, vesicle size and structure, and pharmacokinetic properties. These lipid formulations have demonstrated comparable clinical efficacy, and reduced nephrotoxicity, in comparison with conventional amphotericin B in adults; none is superior in effectiveness to conventional amphotericin B. No studies have compared the safety and effectiveness of lipid preparations with conventional amphotericin B in neonates.

Lackner and coworkers [338] reported successful use of a lipid formulation of amphotericin B, in a daily dose of 5 mg/kg, in two premature infants with disseminated fungal infections. In addition, Weitkamp and associates reported use of this preparation in a daily dose of 1 to 5 mg/kg in 21 low birth weight infants with *Candida* infections and demonstrated its efficacy without apparent nephrotoxicity [693]. Scarcella and colleagues [694] also reported using a lipid formulation of amphotericin B in 44 infants with severe fungal infections. Using a daily dose of 1 to 5 mg/kg, they reported transient hypokalemia but successful outcomes in 32 infants, but 12 infants of very low birth weight died.

## 5-FLUCYTOSINE

5-Flucytosine, a fluoropyrimidine, has been shown to have in vitro activity against some fungi [674,695–697]. It has been used in combination with conventional amphotericin B for an additive antifungal effect for the treatment of disseminated candidiasis and cryptococcosis. The drug is absorbed well from the gastrointestinal tract, and, with doses of 100 to 150 mg/kg, serum levels vary, ranging from 17 to 44 μg/mL [698]. In the cerebrospinal fluid, levels of 5-flucytosine may be as high as 88% of serum concentrations [699]. The drug is administered orally in a total daily dose of 50 to 150 mg/kg, given in four divided doses, for 2 to 6 weeks in adults. Experience with this agent in infants is increasing. Rapid emergence of resistance of fungi after initiation of flucytosine therapy has been reported for *Candida* and for *C. neoformans* [695–700]. Flucytosine has been used extensively in infants and children receiving amphotericin B [701–704]. Few untoward side effects have been noted, even with prolonged use. Toxic effects of flucytosine include transient neutropenia and hepatocellular damage [705]. Because the drug is cleared by the kidneys, the dose should be reduced and serum levels determined in infants with impaired renal function. Accumulation of flucytosine in the blood can result in serious toxicity to the bone marrow.

## FLUCONAZOLE AND ITRACONAZOLE

Fluconazole is an azole antifungal agent and is available in an intravenous and an oral preparation. This agent has been shown to achieve good penetration into cerebrospinal fluid, ocular fluid, and skin [706]. It is effective against many fungi, including *Candida*, *Coccidioides*, and dermatophytes. Its use in neonates has been limited. Wiest and associates [707] used fluconazole in a premature infant with disseminated candidiasis unresponsive to amphotericin B and flucytosine. The infant received 6 mg/kg per day intravenously, with peak and trough serum levels of 10.3 and 6.98 mg/mL, respectively. Gürses and Kalayci [708] reported successful use of fluconazole alone in a premature infant with candidal meningitis. Dreissen and coworkers [709,710] in two reports indicated that fluconazole was effective and associated with fewer side effects than those observed with amphotericin B. A review of 62 episodes of neonatal candidemia revealed that fluconazole was used as the first-line agent in 6 episodes, with successful eradication of infection in five of the episodes. Fluconazole was used as an alternative agent in another 13 episodes, with eradication of infection in 8 of the 13. Fluconazole was well tolerated [711]. Fluconazole also has been used in pregnancy without harmful effects on the fetus [712].

Itraconazole, another azole antifungal agent, has had limited use in neonates. Bhandari and Narange [713] reported its use in two premature infants with disseminated candidiasis. Each received 10 mg/kg per day in two divided doses for 3 and 4 weeks, respectively. Both infants did well without any evidence of toxicity. A pharmacokinetic study of oral itraconazole in infants and children 6 months to 12 years of age demonstrated potentially therapeutic concentrations with a daily dose of 5 mg/kg. Itraconazole was well tolerated [714]. Only limited data are available on use of itraconazole in neonates.

## VORICONAZOLE

Voriconazole is a second-generation antifungal triazole with a broad spectrum of activity, excellent oral bioavailability, and a good safety profile in adults [210]. Voriconazole is approved by the FDA for use in adults for treatment of invasive aspergillosis and in salvage therapy for infections caused by *Scedosporium* and *Fusarium* species. Voriconazole has been successfully used to treat disseminated infection caused by *Trichosporon* species. Data are available that support the safety and efficacy of voriconazole for the treatment of invasive fungal infections in children 9 months to 15 years of age. Only one study, however, has reported pharmacokinetic data in young infants [211].

Treatment with voriconazole in 69 children with aspergillosis, scedosporiosis, and other invasive fungal infections resulted in favorable outcomes in patients who were intolerant of or refractory to conventional antifungal therapy [715]. The dosage was 6 mg/kg administered every 12 hours intravenously on day 1, followed by 4 mg/kg every 12 hours, until clinical improvement allowed a change to oral therapy at a dose of 100 or 200 mg twice a day for patients weighing less than 40 kg or 40 kg or greater, respectively.

## ECHINOCANDINS: CASPOFUNGIN

Echinocandins are cyclic hexapeptides with an N-acyl aliphatic or aryl side chain that expands the antifungal spectrum to include *Candida* species, *Aspergillus* species, and *P. jiroveci*, but not *C. neoformans*. Echinocandins are administered only parenterally because of their large molecular size. They inhibit the biosynthesis of 1,3-beta-glucans, which are key constituents of the fungal cell wall. The enzyme system for 1,3-beta-glucan synthesis is absent in mammalian hosts.

Echinocandins that currently are in use include caspofungin, micafungin, and anidulafungin. Caspofungin has been approved by the FDA for salvage therapy in adults with invasive aspergillosis. The echinocandins have demonstrated in vivo activity against esophageal candidiasis and disseminated candidiasis in adults. Hepatotoxicity has been observed at very high doses. Data on use in infants are very limited, however, and studies are needed to determine the pharmacokinetics, optimal doses, and indications for echinocandins, and their effectiveness, in infants and children [716].

## GRISEOFULVIN

Griseofulvin has significantly altered the morbidity associated with dermatophyte infection. This drug is deposited in epidermal structures before keratinization. As keratinized areas are exfoliated, they are replaced by noninfected tissue. In patients with tinea capitis, it may be necessary to clip the hair frequently because as growth occurs, the ends of hairs may continue to harbor viable fungus. The oral dose of griseofulvin is 10 mg/kg per day for 7 to 10 days. Occasionally, a daily dose of 20 to 40 mg/kg is necessary for cure. In some instances, therapy must be continued for 3 weeks. Data on the use of griseofulvin in newborns are limited. Ross [717] reported use of griseofulvin in an infant 1 month of age at a daily dose of 10 mg/kg for 4 weeks without untoward effects.

Griseofulvin is derived from a species of *Penicillium*, and cross-sensitivity may exist between penicillin and griseofulvin. The incidence of hypersensitivity reactions to griseofulvin in patients allergic to penicillin, however, has not been reported. The most common untoward reaction to griseofulvin is rash. Urticaria and angioneurotic edema are occasional findings, and elevation of transaminases may occur. In one report, griseofulvin was shown to cross the placenta in low concentrations, but fetal effects were not discussed [718]. A study comparing griseofulvin with terbinafine [719], and case reports of successful treatment of tinea capitis with itraconazole and fluconazole, suggest that all of these antifungal agents can be used as alternative agents with better tolerability and fewer side effects [720].

CHAPTER 35

# HEALTHCARE–ASSOCIATED INFECTIONS IN THE NURSERY

**Susan E. Coffin ✪ Theoklis E. Zaoutis**

## CHAPTER OUTLINE

Neonates, especially premature neonates who require intensive medical care, are among the patients at highest risk for nosocomial or health care–associated infections (HAIs). Although the rate of HAIs varies with the specific patient population and institution, some series have reported that more than 20% of critically ill neonates who survive more than 48 hours acquire a nosocomial infection [1–3]. Neonatal HAIs are associated with significant morbidity, mortality, and excessive direct health care costs [3]. Prevention of these infections should be a major priority in all neonatal intensive care units (NICUs) and nurseries. The most important risk factors for HAIs in neonates, gestational age and birth weight, cannot be modified. Close attention to clinical practice and the patient care environment is mandatory to minimize the risk of infections. This chapter reviews the epidemiology, microbiology, pathogenesis, and prevention of neonatal HAIs.

## SPECIAL ISSUES FOR NEONATES

The innate and adaptive arms of the neonatal immune system are functionally less mature than that of older infants, children, and adults (see Chapter 4). Compared with term infants, preterm infants have less developed specific components of the innate immune system, particularly factors that maintain physiologic barriers. Immature and easily damaged skin is a major factor in the relative immunocompromised state of preterm infants. Iatrogenic breeches in skin integrity, such as those caused by percutaneous medical devices and surgical wounds, also constitute a significant risk.

Although the cellular precursors of the human immune system are present around the beginning of the second trimester, T cells, neutrophils, monocytes, and the complement pathways are functionally impaired at this time. Neonatal neutrophils show decreased chemotaxis, diminished adherence to the endothelium, and impaired phagocytosis (see Chapter 4) [4,5]; neonatal complement levels and opsonic capacity also are reduced, particularly in premature neonates. In addition, immature T-cell function results in diminished production of cytokines, T-cell killing of virally infected cells, and B-cell differentiation and maturation.

Passively acquired maternal IgG is the sole source of neonatal IgG. Because transplacental transfer of maternal IgG occurs primarily in the third trimester, the serum IgG levels of many preterm neonates are very low. Soon after birth, maternal IgG levels begin to decline, and neonatal production of antigen-specific immunoglobulins begins. Serum IgG concentrations reach about 60% of adult levels by 1 year of age in term neonates [6]. Given the incomplete transfer of maternal IgG and an impaired ability to produce antigen-specific immunoglobulins, premature infants typically have significantly lower levels of serum IgG than their term counterparts, a difference that can persist throughout the 1st year of life. Developmental issues of other organ systems can also affect the risk of HAIs. The immature gastrointestinal tract, characterized by reduced acidification of gastric contents and the fragile integrity of the intestinal epithelium, provides another potential portal of entry for pathogens.

Colonization resistance, the incomplete passive protection associated with colonization of skin and mucous membranes with "normal flora," also provides protection from invasive infections caused by pathogenic or commensal bacteria. The in utero environment is sterile; however,

DOI: 10.1016/B978-1-4160-6400-8.00035-3

colonization begins within the first few days of life. The acquisition of normal colonizing flora is disrupted in hospitalized newborns for various reasons, including the presence of pathogenic bacteria in the hospital environment and on the hands of health care workers, the frequent use of antimicrobial agents, and exposure to invasive procedures. As a result, the microflora of infants in the NICU can be markedly different from healthy term infants [7,8]. Multidrug-resistant coagulase-negative staphylococci (CoNS) and *Klebsiella*, *Enterobacter*, and *Citrobacter* species colonize the skin and the respiratory and gastrointestinal tracts of a high proportion of NICU neonates by the 2nd week of hospitalization [9–12]. In addition, hospitalized neonates can become colonized with *Candida* and other yeasts [13–16].

# EPIDEMIOLOGY

## INCIDENCE

The incidence of HAIs varies markedly by birth weight, gestational age, underlying conditions, and exposure to medical devices [17]. Reported rates of specific infections in similar patient populations differ dramatically by institution. In the past, much of this variation likely arose from differences in patient populations and clinical practices. The patient safety movement has resulted in marked reductions in the rates of many specific HAIs in numerous NICU settings, however. The risk of HAIs previously reported is likely greater than that currently experienced by many neonatal patients.

In 1999, a nationwide multicenter surveillance study, the Pediatric Prevention Network (PPN) Point Prevalence Survey, was undertaken to determine the point prevalence of and to define risk factors associated with nosocomial infections in NICU patients [18]. This study included 827 infants from 29 NICUs. Of the 827 infants, 94 (11.4%) had an active nosocomial infection on the day of the survey. Bacteremia accounted for 53% of infections. Lower respiratory tract infections; ear, nose, or throat infections; and urinary tract infections accounted for 13%, 9%, and 9% (Table 35–1).

In contrast to the NICU setting, the frequency of nosocomial infection in well-infant nurseries has been estimated to be 0.3% to 1.7% [19–21]. Generally, non–life-threatening infections such as conjunctivitis account for most infections in the well-infant population. The remainder of this chapter focuses almost entirely on nosocomial infections in NICUs.

## MATERNALLY ACQUIRED INFECTIONS

Differentiating maternally acquired and hospital-acquired infections can be difficult. Surveillance definitions typically describe nosocomial infections as infections that arise 2 or more days after initial admission to a nursery or NICU. No precise time point or definition perfectly discriminates infections that clinically were likely attributable to vertical transmission from infections transmitted within the NICU. Approximately 90% of hospitalized neonates with an infection presumed to be of maternal origin had onset of symptoms within 48 hours of birth. Maternally acquired bloodstream infections were more likely to be caused by group B streptococci, other streptococci, and *Escherichia coli* and were rarely caused by CoNS [22].

## NONMATERNAL ROUTES OF TRANSMISSION

Nonmaternal routes of transmission generally can be divided into three categories: contact (from either direct or indirect contact from an infected person or a contaminated source), droplet (from large respiratory droplets that fall out of the air at a maximum distance of 3 feet), and airborne (from droplet nuclei, which can remain suspended in air for long periods and as a result travel longer distances). Specific microorganisms can be spread by more than one mechanism; in most instances, a single mode of spread predominates, however. The U.S. Centers for Disease Control and Prevention (CDC) has developed a system of precautions to prevent the spread of HAIs that is based on these modes of transmission [23].

Most neonatal HAIs are caused by the infant's own flora. The "abnormal flora" of the neonate residing in the NICU is determined at least in part, however, by the NICU environment and the hands of health care workers. Contact transmission of bacteria, viruses, and fungi on the hands of health care workers is arguably the most important, yet seemingly preventable mechanism by which potentially

**TABLE 35–1** Distribution of Infections Acquired in the Neonatal Intensive Care Unit by Birth Weight and Site

pathogenic organisms are spread. Poor compliance with hand hygiene has been repeatedly shown as a cause of outbreaks and transmission of resistant microorganisms [24–27]. With use of molecular techniques, even organisms typically considered to originate solely from normal flora (e.g., CoNS) have been shown to have clonal spread in the hospital setting, suggesting contact transmission by means of the hands of health care workers [28,29].

Transmission via contaminated inanimate objects also occurs and has been described as a potential mechanism of spread of pathogens in multiple NICU outbreaks [27,30,31]. Implicated items have included linens, medical devices, soap dispensers, and breast pumps. These observations highlight the need for careful attention to disinfecting items shared among infants.

Spread of infection through large respiratory droplets is an important mode of transmission for pertussis and certain respiratory viruses. The early identification and appropriate use of precautions for suspected cases are particularly important for nurseries that admit infants from the community. In addition, an ill adult, either a health care worker or a parent, can be the source of these infections in the NICU. Measles, varicella, and pulmonary tuberculosis are usually spread via the airborne route by means of droplet nuclei, but are not typical risks in a nursery or NICU.

Other sources of HAIs include contaminated infusions, medications, and feeding powders or solutions, which can be either intrinsically or extrinsically contaminated and have been reported as the source of outbreaks caused by a variety of different pathogens. It is important when possible to mix infusions in a controlled environment (usually the pharmacy), to avoid multiuse sources of medication, and to use bottled or sterilized feeding solutions when breast milk is unavailable.

## RISK FACTORS FOR HEALTH CARE–ASSOCIATED INFECTIONS

### Patient-Related Factors

As discussed earlier, infants in NICUs have intrinsic factors that predispose them to infection, such as an immature immune system and compromised skin or mucous membranes. In addition, multiple extrinsic factors play important roles in the development of infection, such as presence of indwelling catheters; performance of invasive procedures; and administration of certain medications, such as steroids and antimicrobial agents.

Although the relationship between birth weight and HAIs is likely confounded by multiple other unmeasured factors, such as immune system immaturity, birth weight remains one of the strongest risk factors for HAIs. Data from the CDC show an inverse association between birth weight and the risk of developing either bloodstream infections or ventilator-associated pneumonia (VAP), even after adjusting for central venous catheter (CVC) and ventilator use [22]. Similarly, in the PPN Point Prevalence Survey, infants weighing 1500 g or less at birth were 2.69 (95% confidence interval 1.75 to 4.14; $P < .001$) times more likely to have an infection than infants weighing more than 1500 g [18].

Severity of illness scores have been developed to derive risk-adjusted rates of morbidity and mortality in NICU patients. Stratification by birth weight is the most common strategy used to risk-adjust NICU infection data. Other scores used by some institutions include the Score for Neonatal Acute Physiology (SNAP) [32] and the Clinical Risk Index for Babies (CRIB) [33]. Risk adjustment using these scores can provide more accurate predictions of neonatal mortality and nosocomial infections, although they are not universally used, even within narrow birth weight strata.

### Medical Devices

The presence of indwelling intravascular or transmucosal medical devices has been identified repeatedly as one of the greatest risk factors for HAIs in neonates. Importantly, these associations persist after adjustment for birth weight [18]. The epidemiology of HAIs related to medical devices is discussed in more detail later.

### Therapeutic Agents

Numerous medications and other therapeutic agents crucial to the survival of infants in the NICU increase risk of infection. The widespread use of broad-spectrum antimicrobial agents has been associated with increased colonization with resistant organisms in many settings, including NICUs [8,17]. In addition to increasing colonization, use of antimicrobial agents increases the risk of invasive infection with resistant bacteria [34] and with fungal pathogens [35]. Other medications can also be associated with the development of HAIs. Infants who receive corticosteroids after delivery are at approximately 1.3 to 1.6 times higher risk for nosocomial bacteremia in the subsequent 2 to 6 weeks than infants who do not receive this intervention [36,37]. In addition, colonization and infection with bacterial and fungal pathogens have been shown to increase with the use of $H_2$ blockers [13,38].

Parenteral alimentation and intravenous fat emulsion have been shown in some studies to increase risk of bloodstream infection in premature infants even after adjustment for other covariables, such as birth weight and CVC use; the pathogenesis of this possible association remains unclear [39,40]. Investigators have suggested that fat emulsions could have a direct effect on the immune system [41]. Alternatively, as with any intravenous fluids, parenteral alimentation has the potential for intrinsic and extrinsic contamination, and fat emulsion especially may serve as a growth medium for certain bacteria and fungi. Finally, total parenteral alimentation and intravenous administration of fats likely delay the normal development of gastrointestinal mucosa because of lack of enteral feeding, encouraging translocation of pathogens across the gastrointestinal mucosa. Other risk factors related to infection include poor hand hygiene and environmental issues, such as understaffing and overcrowding [42–44].

## ETIOLOGIC AGENTS

The microbiology of neonatal HAIs is diverse (Table 35–2). Detailed discussions of the microbiology of sepsis and meningitis and of specific organisms can be found in other chapters.

**TABLE 35–2** Most Common Nosocomial Pathogens in Neonatal Intensive Care Unit Patients: Distribution by Site

| | No. Infections (%) | | | | |
|---|---|---|---|---|---|
| **Pathogen** | **Bloodstream** | **EENT** | **GI** | **Pneumonia** | **Surgical Site** |

## COAGULASE-NEGATIVE STAPHYLOCOCCI

Since the early 1980s, CoNS have been the most common cause of HAIs in the NICU [43]. National Nosocomial Infections Surveillance (NNIS) and PPN surveillance data estimate that 32% of total pathogens and 48% to 51% of bloodstream infections are caused by these organisms [18,22]. Although an infrequent cause of fatal infection, bacteremia caused by CoNS has been associated with prolonged NICU stay and increased hospital charges, even after adjustment for birth weight and severity of illness on admission [45]. A 10-year, prospective, multicenter Australian study found that 57% of all late-onset infections during the study period were due to CoNS. Molecular techniques suggest that infections caused by *Staphylococcus epidermidis* can result from clonal dissemination and that there is often concordance between the strains infecting infants and strains carried on the hands of health care workers [28,46,47]. In one study, four clones accounted for 43 of 81 study strains (53%) [28]. This finding suggests that a significant proportion of CoNS infections may be preventable by strict adherence to infection control practices. The fact that a hand hygiene campaign was associated with increased hand hygiene compliance and a lower rate of CoNS-positive cultures further supports this contention [48].

## OTHER GRAM-POSITIVE BACTERIA

*Enterococcus* accounts for approximately 10% of all neonatal HAIs, 6% to 15% of bloodstream infections, 0% to 5% of cases of pneumonia, 17% of urinary tract infections, and 9% of surgical site infections [18,22]. Sepsis and meningitis are common manifestations of enterococcal infection during NICU outbreaks [48–50]. The presence of a nonumbilical CVC, prolonged presence of a CVC, and bowel resection all have been identified as independent risk factors for enterococcal infections in NICU patients [50]. Because *Enterococcus* colonizes the gastrointestinal tract and can survive for long periods on inanimate surfaces, the patient's environment may become contaminated and, along with the infant, serve as a reservoir for ongoing spread of the organism.

Historically, before the recognized importance of hand hygiene and the availability of antimicrobial agents, group A streptococci were a major cause of puerperal sepsis and fatal neonatal sepsis. Although less common now, group A streptococci remain a cause of outbreaks in nurseries and NICUs [51–54]. Group A streptococci–associated clinical manifestations include severe sepsis and soft tissue infections. Molecular techniques have enhanced the ability to define outbreaks, and use of these techniques has suggested that transmission can occur between mother and infant, between health care worker and infant, and between infants—probably indirectly on the hands of health care workers [52,53]. In one recurring outbreak, inadequate laundry practices seemed to be a contributing factor [55].

Data from the CDC have shown that group B streptococci infections account for less than 2% of non–maternally acquired nosocomial bloodstream and pneumonia infections [22]. Numerous studies from the 1970s and 1980s showed nosocomial colonization of infants born to women negative for group B streptococci [56–60]. These studies suggested a rate of transmission to infants born to seronegative mothers of 12% to 27% [57,58]. A case-control study evaluating risk factors for late-onset infection caused by group B streptococci showed that premature birth was a strong predictor [61]. In that study, 50% of the infants with late-onset infection

caused by group B streptococci were born at less than 37 weeks of gestation (compared with 15% of controls), and only 38% of the mothers of these infants were colonized with group B streptococci, suggesting possible nosocomial transmission of group B streptococci during the NICU stay.

## GRAM-NEGATIVE BACTERIA

Organisms from the Enterobacteriaceae family have long been recognized as an important cause of HAIs, including sepsis, pneumonia, urinary tract infections, and soft tissue infections; morbidity and mortality rates frequently are high [62]. *Enterobacter* species, *Klebsiella pneumoniae*, *E. coli*, and *Serratia marcescens* are the members of Enterobacteriaceae most commonly encountered in the NICU. Many outbreaks owing to gram-negative bacteria have been reported. Underlying causes of these outbreaks include contaminated equipment [63–66], formula or breast milk [66–71], and intravenous fluids [72–74]; understaffing; overcrowding; and poor hand hygiene practices [75–78]. The origins of these organisms are often unclear, although many authors hypothesize that at least some episodes of gram-negative bacteremia are a consequence of intestinal translocation. This hypothesis is consistent with the observation that enteric feedings have been associated with a reduced risk of gram-negative infections [79].

*Pseudomonas aeruginosa*, an opportunistic pathogen that can persist in relatively harsh environments, frequently has been associated with HAIs and outbreaks in NICUs. Nosocomial *P. aeruginosa* infections vary in their clinical presentation, but the most common manifestations are respiratory; ear, nose, or throat; and bloodstream infections [18]. *P. aeruginosa* infections, particularly bloodstream infections, have been associated with a very high mortality rate [80]. Risk factors for infection include feeding intolerance, prolonged parenteral alimentation, and long-term intravenous antimicrobial therapy [80]. Outbreaks owing to *P. aeruginosa* have been linked to contaminated hand lotion [81], respiratory therapy solution [82], a water bath used to thaw fresh frozen plasma [83], a blood gas analyzer [84], and bathing equipment [85]. Health care workers and their contaminated hands also have been linked with *Pseudomonas* infections in the NICU. In a study of a New York outbreak, recovery of *Pseudomonas* species from the hands of health care workers was associated with older age and history of use of artificial nails [86]. This and other studies suggest that the risk of transmission of *Pseudomonas* to patients is higher among health care workers with onychomycosis or who wear long artificial or long natural nails [86,87]. As a result of these and other findings, the CDC revised its 2002 hand hygiene recommendations to include a recommendation against the presence of health care workers with artificial fingernails in intensive care units [88].

## MULTIDRUG-RESISTANT ORGANISMS

*Staphylococcus aureus* has frequently been identified as a cause of nosocomial infection and outbreaks in well-infant nurseries and NICUs. Methicillin-resistant *S. aureus* (MRSA) has become a serious nosocomial pathogen, and outbreaks have been reported in many areas of hospitals, including nurseries [89–91]. With the emergence of community strains of MRSA, nosocomial transmission of MRSA with the molecular phenotype of either community-associated or hospital-associated strains has been shown [92,93]. In addition to the usual manifestations of neonatal nosocomial infection, *S. aureus* HAIs (caused by methicillin-sensitive strains or MRSA strains) can manifest as skin infections [94], bone and joint infections [95], parotitis [96], staphylococcal scalded skin syndrome [97,98], toxic shock syndrome [89], and disseminated sepsis.

Direct contact is the presumed mechanism of most instances of *S. aureus* transmission. Several distinct reservoirs of MRSA have been identified and associated with MRSA outbreaks, including parents, visitors, and health care workers [90,97,99,100]. Understaffing and overcrowding have been associated with *S. aureus* outbreaks in NICUs [90,101]. The potential for airborne transmission has been suggested by "cloud babies," described by Eichenwald and colleagues [102], in which the respiratory secretions or desquamated skin from a colonized infant carry *S. aureus* over relatively long distances. "Cloud" health care workers also have been described; in such cases, the point source of an outbreak was determined to be a colonized health care worker with a viral respiratory infection [94,103]. Parents can also transmit MRSA to their newborn infants on passage through a colonized birth canal or postpartum handling [104,105].

The emergence of vancomycin-resistant enterococci (VRE) is a concern in all hospital settings, and several VRE outbreaks have been reported in NICUs [106,107]. In neonates, VRE seem to cause clinical syndromes indistinguishable from syndromes caused by susceptible enterococci [50]. Vancomycin use, which is especially prevalent in the NICU, has increased markedly and has probably contributed to the growing prevalence of resistant gram-positive organisms in neonatal patients [108]. More recent observations suggest that clinical infections caused by VRE may signal the presence of a larger reservoir of VRE among asymptomatic colonized infants, and some authors have suggested that active surveillance may be required to interrupt ongoing transmission [109,110].

Over the past decade, the array and prevalence of resistant gram-negative organisms have rapidly expanded. Extended-spectrum β-lactamases (ESBLs) are plasmid-mediated resistance factors produced by members of the Enterobacteriaceae family. ESBLs inactivate third-generation cephalosporins and aztreonam. *K. pneumoniae* and *E. coli* are the organisms most commonly recognized as ESBL-producing organisms, but other ESBL-producing gram-negative bacilli are being increasingly identified. NICU outbreaks caused by other ESBL-producing organisms have been identified; transfer of ESBL-carrying plasmids to other Enterobacteriaceae organisms has been shown in several NICU outbreaks [111,112]. Two mechanisms of acquisition of resistant gram-negative organisms have been shown through molecular epidemiologic investigations: patient-to-patient transfer (presumably via contaminated health care worker hands or medical equipment) and de novo emergence as a consequence of antibiotic exposure [113,114].

## FUNGI

*Candida* species are the third most common pathogen identified in patients with late-onset sepsis and are associated with morbidity and mortality rates similar to those observed with sepsis from gram-negative bacteria [115]. More recent reports have also linked neonatal candidiasis to increased neurodevelopmental impairment in infancy [116] and retinopathy of prematurity [117] and have quantified the cost of an episode of candidemia in the NICU to be $28,000 to $39,000 [118,119].

Fridkin and colleagues [120] reported on data from the NNIS network, including 128 NICUs covering 130,523 patients over a 10-year period ending in 2004. Of 1997 cases of candidemia in these patients, 57.9% were *Candida albicans*, 33.7% were *Candida parapsilosis*, 3.8% were *Candida tropicalis*, 2% were *Candida glabrata*, and 0.2% were *Candida krusei*. Over time, there was an overall decrease in candidemia in neonates weighing less than 1000 g, but no change in the distribution of *Candida* species. The combined mortality rate for neonates with candidemia was 13%, which did not significantly differ among infecting species. There was variability, however, with respect to the incidence of candidemia in different NICUs, ranging from 2.4% to 20.4%.

A retrospective cohort study of neonatal candidiasis using the 2003 Kids Inpatient Database reported the incidence of candidiasis at 15 per 10,000 NICU admissions [119]. Two thirds of the cases occurred in neonates with a birth weight of less than 1000 g. Of these patients, neonates with extremely low birth weight were twice as likely to die as propensity-matched neonates with extremely low birth weight without candidiasis. The overall mortality attributable to candidiasis in neonates with extremely low birth weight was 11.9%.

Many risk factors have been associated with neonatal candidemia. Colonization likely precedes infection, and this can occur either vertically (via the maternal genitourinary tract) or horizontally (nosocomial spread). The relative roles of gastrointestinal tract colonization and enteric translocation versus skin surface colonization and catheter-related infection are unclear and not mutually exclusive [121]. A prospective study, including 35 infected neonates, suggested that risk factors for candidemia included gestational age 32 weeks or younger, Apgar score less than 5, shock, disseminated intravascular coagulation, intralipid use, parenteral nutrition, CVCs, $H_2$ blockers, intubation, and length of stay more than 7 days [35]. Various other studies have largely confirmed or expanded on these results, including two more recent reports. A prospective, multicenter study by Benjamin and coworkers [116] analyzed data from 320 infants with extremely low birth weight and invasive candidiasis and found birth weight less than 750 g, male gender, delayed enteral feeding, and cephalosporin use all to be associated with disease. Cotten and associates [122] reported on 3702 infants with extremely low birth weight in 12 NICUs, linking candidiasis with third-generation cephalosporin use.

Fluconazole prophylaxis at dosage at 3 mg/kg or 6 mg/kg twice weekly reduces rates of candidemia in premature neonates in NICUs that have a high incidence of candidemia [123,124]. Because there are limited safety data on the prolonged use of fluconazole in neonates, the Infectious Diseases Society of America recommends routine fluconazole prophylaxis only for premature infants and infants with the extremely low birth weights in nurseries that have a high incidence of invasive candidiasis [125].

*Malassezia* species, which are lipophilic yeasts, frequently colonize NICU patients. In one French study, 30 of 54 preterm neonates (56%) became colonized with *Malassezia furfur* [126]. *Malassezia pachydermatis*, a zoonotic organism present on the skin and in the ear canals of healthy dogs and cats, also has been associated with nosocomial outbreaks in NICUs [126,127]. In one report, the outbreak seemed to be linked to colonization of health care workers' pet dogs [126].

Invasive mold infections are a rare cause of nosocomial infection in neonates, but when they occur, they are associated with a high mortality rate. *Aspergillus* infections may manifest as pulmonary, central nervous system, gastrointestinal, or disseminated disease. A cutaneous presentation, with or without subsequent dissemination, seems to be the most common presentation for hospitalized premature infants without underlying immunodeficiency [128,129]. Often, skin maceration is the presumed portal of entry. In a series of four patients who died of disseminated *Aspergillus* infection that started cutaneously, a contaminated device used to collect urine from the male infants was implicated [129]. Similarly, contaminated wooden tongue depressors, used as splints for intravenous and arterial cannulation sites, were associated with cutaneous infection owing to *Rhizopus microsporus* in four premature infants [130]. In addition to preterm birth, use of broad-spectrum antimicrobial agents, steroid therapy, and hyperglycemia are thought to be risk factors for mold infection.

Even zoophilic dermatophytes have been described as a source of nosocomial infection in neonates. In one report, five neonatal cases in one unit were traced to an infected nurse and her cat [131]. Prolonged therapy for the nurse and her cat was necessary to clear their infections.

## VIRAL PATHOGENS

Nosocomial viral infections can be a significant problem for neonates [132]. Introduction of common viral pathogens into the NICU can be associated with (1) admission of infants from the community, (2) health care workers who work while ill or infectious, and (3) visitors.

### Enteric Viruses

Although many pathogens can cause nosocomial gastroenteritis, rotavirus is responsible for 95% or more of viral infections in high-risk nurseries, including the NICU [22,133]. The clinical picture of rotavirus infections in newborns can vary markedly; there are many reports of asymptomatic rotavirus infection in nurseries [134]. In addition, rotavirus can be manifested as frequent and watery stools in term infants and as abdominal distention and bloody, mucoid stools in preterm neonates [133,135]. A high titer of virus is excreted in stool of infected persons, and the organism is viable on hands and in the environment for relatively prolonged periods [136,137].

Attention to hand hygiene and disinfection of potential fomites are crucial in preventing spread of infection. Rotavirus outbreaks in NICUs have been associated with poor hand hygiene, ill health care workers, and ill visitors [137]. Rotaviruses [138] and other enteric viruses, including norovirus [139], astrovirus [140], and toroviruses [141], have been associated with necrotizing enterocolitis.

### Respiratory Viruses

Respiratory viruses, including influenza A virus, parainfluenza virus, coronavirus, respiratory syncytial virus, and adenovirus, have been reported to cause nosocomial infections in NICU patients [142–145]. Associated clinical findings include rhinorrhea, tachypnea, retractions, nasal flaring, rales, and wheezing, but illness can also be manifested as apnea, sepsis-like illness, and gastrointestinal symptoms [137,145–147]. Identified risk factors for acquisition vary from study to study, but have included low birth weight, low gestational age, twin pregnancy, mechanical ventilation, and high CRIB score [143–146]. Contact and droplet transmission are the most common modes of spread of infection—highlighting the importance of scrupulous hand hygiene and adherence to transmission-based precautions.

### Enteroviruses

Numerous nursery and NICU outbreaks of enteroviral infection have been reported [148–150]. In a neonate with enteroviral infection, clinical manifestations can range from mild gastroenteritis to a severe and fulminant sepsis-like syndrome or meningitis and encephalitis. The latter presentation can be associated with a high mortality rate [149]. Several outbreak investigations have shown the introduction of enterovirus into a nursery via vertical transmission to an index case, with subsequent horizontal spread [149,151]. Enteroviruses are typically shed in the stool of infected neonates for long periods, providing a reservoir of organisms that can be transmitted when breaches of infection control practices occur.

### Cytomegalovirus

Congenital cytomegalovirus (CMV) infection can be asymptomatic or fulminant. Postnatally acquired CMV infections almost always follow a benign course in healthy term infants. Postnatal CMV infection in premature infants can be severe, however, and associated with hepatitis, bone marrow suppression, or pneumonitis [152–154]. The incidence of postnatal CMV infections in preterm infants has decreased significantly with the routine use of CMV-seronegative blood products. At present, most postnatal CMV infections are acquired through breast milk [155]. Approximately one third of infants who are breastfed by mothers with CMV detected in breast milk can develop infection [156]. In one study, approximately 50% of these infants had clinical features of infection, and 12% presented with a sepsis-like syndrome. At present, no proven, highly effective method is available for removing CMV from breast milk without destroying its beneficial components. Some data suggest, however, that freezing breast milk before use may decrease the CMV titer, limiting subsequent transmission [157]. Person-to-person transmission within the NICU has also been documented [158,159], but the extent to which this occurs is controversial [160]. More detailed information on the clinical features and management of CMV is presented in Chapter 23.

### Herpes Simplex Virus

Most neonates with herpes simplex virus (HSV) acquire the infection from their mother, although nursery transmission of HSV infection has been described [161–163]. Although the precise mechanism of transmission remains unclear in some cases, contact transmission has been commonly implicated. Presumed patient-to-patient transmission apparently via the hands of health care workers has been described [163]. Additionally, HSV can frequently be recovered from the hands of parents and health care worker with herpes labialis [164]. Strict attention to hand hygiene is critical to prevent nursery spread of HSV. Health care workers with herpetic whitlow are typically restricted from patient contact until the lesion is healed. An in-depth discussion of the clinical features and management of HSV is provided in Chapter 26.

### Varicella-Zoster Virus

With the adoption of varicella vaccine and health care worker screening for varicella immunity, nosocomial transmission of varicella-zoster virus has become rare [165]. Infants at greatest risk are premature infants born at less than 28 weeks of gestation who did not receive transplacental maternal antibodies. Transmission is most likely to occur from an adult with early, unrecognized symptoms of varicella because the virus is excreted in respiratory secretions 24 to 48 hours before onset of the characteristic rash. Management of neonates exposed to and infected with varicella-zoster virus is discussed in Chapter 22.

### Hepatitis A

NICU outbreaks of hepatitis A have been reported and have typically been recognized after diagnosis of a symptomatic adult [166–168]. Transmission has been documented via blood transfusion from a donor with acute infection [168]. In addition, indirect patient-to-patient transmission through fomites or health care worker hands can occur when there are subclinical cases (as is typical in neonatal hepatitis A infection) and lapses in the adherence to standard precautions. Neonatal hepatitis is discussed in depth in Chapter 25.

## DEVICE-RELATED INFECTIONS

## CATHETER-ASSOCIATED BLOODSTREAM INFECTIONS

### Epidemiology and Pathogenesis

Bloodstream infections account for a large proportion of all HAIs in NICU patients [18], and most are related to the use of an intravascular catheter [169]. Peripheral intravenous catheters are the most frequently used devices for neonatal patients. When a longer duration of access is

necessary, nontunneled CVCs such as umbilical catheters or peripherally inserted central catheters are commonly used [170].

The CDC has tracked rates of HAIs for many years, originally in the NNIS system and more recently in the National Healthcare Safety Network (NHSN). Using standardized definitions, NHSN reported rates of HAIs among 127 participating level III NICUs. Data from 2006–2007 that were published by NHSN revealed that the mean rate of central catheter–associated bloodstream infections ranged from 3.7 per 1000 catheter days for infants with birth weights less than 750 g to 2 per 1000 catheter days for infants with birth weights greater than 2500 g. Rates of umbilical catheter–associated bloodstream infections were 4.7 per 1000 catheter days for infants with birth weights less than 750 g and 1 per 1000 catheter days for infants with birth weights greater than 2500 g (Table 35–3) [171].

The origins of invasive organisms in neonates with catheter-associated bloodstream infections are often debated. Molecular analysis has show that most CoNS isolated from neonates with catheter-associated bloodstream infections are concordant with isolates recovered from lumens of catheter hubs, suggesting that many of these episodes of infection may be a consequence of intraluminal contamination, potentially associated with inadequate disinfection before catheter access [172]. Contamination of the catheter exit site has also been identified as a mechanism of infection in pediatric and adult patients. Finally, infusion of contaminated fluids, medications, or blood products can also give rise to catheter-associated bloodstream infections.

## Prevention and Control

Several advisory groups, including the CDC, the Vermont-Oxford Collaborative, and the Infectious Diseases Society of America, have published detailed recommendations of strategies to reduce the incidence of catheter-associated bloodstream infections that strike a balance between patient safety and cost-effectiveness [169,173,174]. A compendium of strategies to prevent specific HAIs has been endorsed by the Society of Healthcare Epidemiologists of America and the Infectious Diseases Society of America and includes detailed information on strategies to prevent catheter-associated bloodstream infections (Table 35–4) [174]. A key strategy to minimize the risk of catheter-associated bloodstream infections is the prompt removal of indwelling catheters when no longer medically necessary. Practices such as early enteral feeding and rapid conversion to oral medications whenever possible can shorten the length of time a patient requires a catheter. Finally, participation in quality improvement activities focused on improved hand hygiene and better adherence to best practices for catheter placement and maintenance has been shown to reduce the rate of catheter-associated bloodstream infections in NICUs [175].

Evidence-based guidelines for the prevention catheter-associated bloodstream infections in all patient populations recommend to avoid catheter placement in the groin because of a higher risk of infection [169]. More recent data in neonatal patients have shown, however, that catheter placement in the lower extremity is not associated with an increased risk of infection in neonates [176]. Umbilical veins and arteries are available for CVC insertion only in neonates. The umbilicus provides a site that can be cannulated easily, allowing for collection of blood specimens and hemodynamic measurements, but soon after birth, the umbilicus becomes heavily colonized with skin flora and other microorganisms. Nonetheless, rates of catheter colonization and catheter-associated bloodstream infections attributable to umbilical catheters are similar to rates associated with other types of CVC. Colonization rates for umbilical artery catheters are estimated to be 40% to 55%; the estimated rate for umbilical artery catheter–related bloodstream infection is 5% [169].

**TABLE 35–3** Rates of Catheter-Associated Bloodstream Infection by Birth Weight Category*

| | Pooled Mean | |
|---|---|---|
| **Birth Weight (g)** | **Umbilical CA-BSI†** | **Non–Umbilical CA-BSI‡** |
| ≤750 | 4 | 3.7 |
| 751–1000 | 2.6 | 3.3 |
| 1001–1500 | 1.9 | 2.6 |
| 1501–2500 | 0.9 | 2.4 |
| >2500 | 1 | 1 |

Colonization rates are 22% to 59% for umbilical vein catheters; rates for umbilical vein catheter–related bloodstream infections are 3% to 8% [169].

Careful skin antisepsis before insertion of an intravascular catheter is crucial to prevention of intravascular device–related bacteremia. The CDC recommends chlorhexidine-based preparations because these products have been found to be superior to povidone-iodine in reducing the risk of catheter colonization (a recognized surrogate marker of catheter-associated bloodstream infections). Although not approved by the U.S. Food and Drug Administration (FDA) for use in infants younger than 2 months of age, some NICUs have reported the off-label use of this product [177].

Antiseptic solutions "locked" into a catheter lumen have been investigated as a strategy to prevent or treat catheter-associated bloodstream infections in adult patients; only a few studies have been performed in patients younger than 1 year of age. In a study performed in a community level III nursery, high-risk infants (infants with very low birth weight and others with critical illnesses) were randomly assigned to have a newly placed peripherally inserted central catheter "locked" several times a day with either a vancomycin-heparin solution or a heparin-only solution. The investigators noted a significant reduction in the incidence of catheter-related bloodstream infections (relative risk 0.13; 95% confidence intervals 0.01 to 0.57) [178]. A single-center randomized clinical trial of fusidic acid–heparin solutions infused and held within a catheter lumen was associated with a significant reduction in the incidence of catheter-associated bloodstream infections (6.6 versus 24.9 per 1000 catheter days; $P < .01$; relative risk 0.28; 95% confidence interval 0.13 to 0.60). The high rate of catheter-associated bloodstream infections in the control group of infants suggests that this intervention might not be beneficial in settings that have already achieved low infection rates [179]. Because many NICUs achieve substantial reductions in the rates of catheter-associated bloodstream infections through application of other evidence-based practices, the role of antiseptic lock solutions needs further investigation.

In 2008, a Cochrane review examined whether prophylactic systemic antibiotics prevented neonatal infection or death. Through systematic review of the published literature, the investigators found only three small studies that evaluated this question. Although the authors observed that use of prophylactic systemic antibiotics was associated with a decreased risk of bloodstream infections, they concluded that this practice could not be recommended because there was no significant difference in overall mortality, and there were significant safety concerns related to the possible selection of resistant organisms [180].

Other strategies that are commonly used by clinicians caring for adult patients are not commonly used to prevent catheter-associated bloodstream infections in NICU patients. Although antiseptic-impregnated catheters are recommended for adult patients [169], these catheters are not available in sizes small enough for neonates. In addition, although the CDC recommends changing the insertion site of peripheral intravenous catheters at least every 72 to 96 hours in adults, data suggest that leaving peripheral intravenous catheters in place in pediatric patients does not increase the risk of complications [181]. The 2002 CDC guidelines recommend that peripheral intravenous catheters be left in place in children until therapy is completed, unless complications occur [169].

## VENTILATOR-ASSOCIATED PNEUMONIA

### Epidemiology and Pathogenesis

Health care–associated pneumonia is the second most common HAI in NICU patients; most of these cases are VAP. Neonatal VAP has been associated with increased direct costs and prolonged length of hospitalization [182]. Gram-negative organisms are the most commonly recovered pathogens from tracheal specimens of patients with VAP [182].

The pathogenesis of VAP is most commonly attributed to one of three different mechanisms: aspiration of secretions, colonization of the aerodigestive tract, or use of contaminated equipment [183]. Specific risk factors for VAP are associated with these basic pathogenic mechanisms and include host characteristics (prematurity, low birth weight, sedation, or use of paralytic agents), exposure to medical devices (endotracheal intubation, mechanical ventilation, orogastric or nasogastric tube placement), and factors that increase bacterial colonization of the aerodigestive tract (broad-spectrum antimicrobial agents, antacids, or $H_2$ blockers) [182,184–186].

### Prevention and Control

Few studies have been performed to assess the effectiveness of VAP prevention strategies in pediatric patients; most commonly used strategies to prevent VAP in NICU patients are based on studies performed in adults. In 2008, infectious disease experts and hospital epidemiologists published a broad review entitled, "Strategies to Prevent Ventilator-Associated Pneumonia in Acute Care Hospitals." This document should serve as a guideline for NICUs working to reduce the rate of VAP in their patients; Table 35–5 provides a summary of these recommendations [183]. The core recommendations are designed to interrupt the three most common mechanisms by which VAP typically develops. An obvious, but key, component of VAP prevention is to minimize the use of invasive mechanical ventilation. This can be accomplished

**TABLE 35–5** Evidence-Based Strategies to Prevent Ventilator-Associated Pneumonia

| |
|---|
| Conduct surveillance for ventilator-associated pneumonia (A-II) |
| Educate health care workers who care for ventilated patients (A-II) |
| Implement practices for disinfection, sterilization, and maintenance of respiratory equipment (A-II) |
| Perform regular oral care (A-I) |
| Ensure patients are maintained in semirecumbent position, unless medical contraindication exists (B-II) |
| Promote use of noninvasive ventilation when possible (B-III) |

*Adapted from Coffin SE, et al. Strategies to prevent ventilator-associated pneumonia in acute care hospitals. Infect Control Hosp Epidemiol 29(Suppl 1):S31–S40, 2008.*

by the use of weaning protocols, daily sedation vacations to assess readiness to wean, and increased use of noninvasive ventilation [187,188].

Practices designed to minimize aspiration of pathogenic organisms include performing regular oral care (even in the absence of teeth), patient positioning in a semirecumbent angle, avoiding gastric overdistention, and avoiding unplanned extubations. A single-center study showed delayed onset of tracheal colonization in intubated infants who were positioned on their side; however, no studies have shown a clear reduction in neonatal VAP associated with strict adherence to this practice [189]. Appropriate placement of enteral feeding tubes should be verified before their use [190,191]. To prevent regurgitation and potential aspiration of stomach contents by a sedated patient, overdistention of the stomach should be avoided by regular monitoring of the patient's intestinal motility, serial measurement of residual gastric volume or abdominal girth, reducing the use of narcotics and anticholinergic agents, and adjusting the rate and volume of enteral feedings [190,191]. Oral decontamination, with the intent of decreasing oropharyngeal colonization, has been studied in adults and seems to reduce the incidence of VAP [192,193]. Many NICUs have already adopted regular oral care as a component of their VAP prevention activities.

Finally, avoidance of $H_2$ blocking agents and proton pump inhibitors in patients without a high risk of stress gastritis may reduce the risk of VAP by minimizing the density of bacterial colonization of the stomach [194]. Two small studies performed in pediatric patients failed to show a significant benefit; however, the authors stressed that additional studies with larger sample sizes are needed to confirm these findings [195,196]. Further studies are needed to define the most important VAP prevention strategies for young infants and to determine the relative contribution of each of these strategies in neonates.

Careful attention to the appropriate disinfection and reprocessing of reusable components of respiratory care equipment is also important [197]. In addition, circuits should be monitored for the accumulation of condensate and drained periodically, with care taken to avoid allowing the condensate, a potential reservoir for pathogens, to drain toward the patient [191]. Other basic infection control measures, such as hand hygiene and standard precautions, can also reduce the risk of VAP and other types of nosocomial pneumonia and are generally recommended for all ventilated patients [183].

## CATHETER-ASSOCIATED URINARY TRACT INFECTIONS

Nosocomial urinary tract infections are commonly identified as the most common cause of HAIs in adults [198]; however, data from NHSN and single-center studies suggest that the incidence of catheter-associated urinary tract infections among hospitalized neonates is significantly lower than observed in adults [171,199]. Gram-negative organisms, yeast, and enterococci are the most frequently reported pathogens [199]. Risk factors that have been specifically identified in young children include prolonged catheterization and young age [199,200]. Although few studies have prospectively evaluated strategies to prevent catheter-associated urinary tract infections in neonates, implementation of the strategies outlined in the document "Strategies to Prevent Catheter-Associated Urinary Tract Infections" is recommended [198].

## VENTRICULAR SHUNT–ASSOCIATED INFECTIONS

Premature infants are at significant risk of intraventricular hemorrhage and may require temporary or permanent diversion of cerebrospinal fluid to manage obstructive hydrocephalus. Placement of cerebrospinal fluid shunts is associated with a significant risk of postoperative infections, either ventriculitis or more superficial surgical site infections. Premature births, prior shunt placement, breeches in aseptic technique during shunt placement, and use of a neuroendoscope have been identified as risk factors for shunt infections [201,202]. Use of antimicrobial-impregnated suture material and shunt catheters are currently being evaluated as possible strategies to reduce the risk of these infections [203–205].

# PREVENTING TRANSMISSION OF HEALTH CARE–ASSOCIATED INFECTIONS

An effective infection control program that focuses on reducing risk on a prospective basis can decrease the incidence of HAIs [206,207]. The principal function of such a program is to protect the infant and the health care worker from risk of HAI in a manner that is cost-effective. Activities crucial to achieving and maintaining this goal include collection and management of critical data relating to surveillance for nosocomial infection and direct intervention to interrupt the transmission of infectious diseases [19].

## SURVEILLANCE

Surveillance is an essential component of infection prevention programs. The definitions provided by the CDC have been widely adopted and provide specific definitions and data collection for the NICU population [208–210]. These definitions do not distinguish, however, late-onset infections caused by transplacentally acquired organisms (e.g., group B streptococcus infections) from more typical nosocomial infections [210]. Distinction between maternal and hospital sources of infection is important, although difficult at times, because control measures designed to prevent acquisition from hospital sources would be ineffective in preventing perinatal acquisition of pathogens [211]. Surveillance for infections in healthy newborns also is challenging because of the typically short length of stay. Infections can develop after discharge, and these are more difficult for infection control practitioners to capture. Methods for postdischarge surveillance have been developed, but because most neonatal infections that occur after discharge are noninvasive [212], such surveillance has not been widely implemented owing to concerns about the cost-effectiveness of these labor-intensive processes.

Surveillance data must be analyzed and presented in a way that facilitates interpretation, comparison directed

internally and with comparable external benchmarks, and dissemination within the organization. Quality improvement tools (e.g., control and run charts) can be useful for these purposes. Statistical tools should be used to determine the significance of findings, although statistical significance should always be balanced with the evaluation of clinical significance [213]. External benchmarking through interhospital comparison is a valuable tool for improving quality of care [214,215], but should be performed only when surveillance methodologies (e.g., case definitions, case finding, data collection methods, intensity of surveillance) [213] can reasonably be assumed to be consistent between facilities.

Infection data must be shared with personnel who can effect change and implement infection control interventions. Written reports summarizing the data and appropriate control charts should be provided to the facility's infection control committee, unit leaders, and members of the hospital administration on an ongoing basis. The interval between reports is determined by the needs of the institution. In addition to formal written reports, face-to-face reports are appropriate in the event of identification of a serious problem or an outbreak. Infection control practitioners can serve as consultants to assist NICU or neonatology service leaders in addressing infection rate increases or outbreak management.

More recently, controversy has emerged over the use of active surveillance cultures to identify infants colonized with multidrug-resistant organisms. Although many adult ICUs have begun to screen all patients routinely on admission for carriage of various multidrug-resistant organisms, this practice has not yet been consistently adopted by NICUs. Factors such as the perceived low rate of carriage of resistant organisms by infants have undoubtedly led some neonatologists to question the need for universal screening on NICU admission. Data have shown, however, that a significant reservoir of resistant organisms can exist in hospitalized neonates. After two patients developed clinical infections owing to VRE, surveillance cultures revealed that more than 15% of other patients in the same unit had unsuspected VRE colonization [109,110].

Some units have adopted regularly scheduled point prevalence surveys as an alternative strategy to universal surveillance. Point prevalence surveys are most useful in units with a known low prevalence of multidrug-resistant organisms and can be used for early detection of increasing rates of carriage of multidrug-resistant organisms. Some NICUs have used active surveillance for carriage of multidrug-resistant organisms to guide programs that have led to the successful eradication of MRSA [216].

## STANDARD AND TRANSMISSION-BASED PRECAUTIONS IN THE NURSERY

The most widely accepted guideline for preventing the transmission of infections in hospitals was developed by the CDC [217]. Updated in 2007, the guideline recommends using two tiers of precautions. The first and most important, standard precautions, was designed for the management of all hospitalized patients regardless of their diagnosis or presumed infection status. The second, transmission-based precautions, is intended for patients documented or suspected to be infected or colonized with highly transmissible or epidemiologically important pathogens for which additional precautions to interrupt transmission are needed.

### Standard Precautions

Standard precautions are designed to reduce the risk of transmission of microorganisms from recognized and unrecognized sources and are to be followed for the care of all patients, including neonates. They apply to blood; all body fluids, secretions, and excretions except sweat; nonintact skin; and mucous membranes. Components of standard precautions include hand hygiene and wearing gloves, gowns, and masks and other forms of eye protection.

#### *Hand Hygiene*

Hand hygiene plays a key role for caregivers in the reduction of nosocomial infection for patients [26,218] and in prevention of HAIs. Hand hygiene should be performed before and after all patient contacts; before donning sterile gloves to perform an invasive procedure; after contact with blood, body fluids or excretions, mucous membranes, nonintact skin, and wound dressings; in moving from a contaminated body site to a clean body site during patient care (i.e., from changing a diaper to performing mouth care); after contact with inanimate objects in the immediate vicinity of the patient; after removing gloves; and before eating and after using the restroom [88]. When hands are visibly soiled or contaminated with proteinaceous materials, blood, or body fluids and after using the restroom, hands should be washed with soap and water.

When hands are not visibly soiled, alcohol-based hand rubs, foams, or gels are an important tool for hand hygiene. Compared with washing with soap and water, use of the alcohol-based products is at least as effective against a variety of pathogens and requires less time, and these agents are less damaging to skin. The CDC "Guideline for Hand Hygiene in the Health Care Setting" calls for use of alcohol hand rubs, foams, or gels as the primary method to clean hands except when hands are visibly soiled [88]. Specific activities that have been independently associated with increased density of pathogens on health care worker hands include skin contact, respiratory care, and diaper changes. Additionally, investigators have shown that the use of gloves during these activities does not fully protect health care workers' hands from bacterial contamination [219]. Programs that have been successful in improving hand hygiene and decreasing nosocomial infection have used multidisciplinary teams to develop interventions focusing on use of the alcohol rubs in the setting of institutional commitment and support for the initiative [26,220,221].

Health care workers should wash hands and forearms to the elbows on arrival in the nursery. A 3-minute scrub has been suggested [67], but consensus on optimal duration of initial hand hygiene is lacking. At a minimum, the initial wash should be long enough to ensure thorough washing and rinsing of all parts of the hands and forearms. Routine hand washing throughout care delivery should consist of wetting the hands, applying product,

rubbing all surfaces of the hands and fingers vigorously for at least 15 seconds, rinsing, and patting dry with disposable towels [88]. Wearing hand jewelry has been associated with increased microbial load on hands; whether this results in increased transmission of pathogens is unknown. Many experts recommend, however, that hand and wrist jewelry not be worn in the nursery [222,223]. In addition, the CDC guideline states that staff who have direct contact with infants in NICUs should not wear artificial fingernails or nail extenders [88]. Only natural nails kept less than ¼ inch long should be allowed; at least one outbreak in an NICU was associated with a health care worker who wore artificial nails [224].

### *Gloves*

Clean, nonsterile gloves are to be worn whenever contact with blood, body fluids, secretions, excretions, and contaminated items is anticipated. The health care worker should change gloves when moving from dirty to clean tasks performed on the same patient, such as after changing a diaper and before suctioning a patient, and whenever they become soiled. Because hands can become contaminated during removal of gloves, and because gloves may have tiny, unnoticeable defects, wearing gloves is not a substitute for hand hygiene. Hand hygiene must be performed immediately after glove removal [23].

### *Gowns*

Personnel in nurseries including the NICU historically have worn cover gowns for all routine patient contact. The practice has not been found to reduce infection or colonization in neonates and is unnecessary [225,226]. Instead, CDC guidelines recommend nonsterile, fluid-resistant gowns to be worn as barrier protection when soiling of clothing is anticipated and in performing procedures likely to result in splashing or spraying of body substances [23]. Possible examples of such procedures in the NICU are placing an arterial line and irrigating a wound. The Perinatal Guidelines of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists recommend that a long-sleeved gown be worn over clothing when a neonate is held outside the bassinette by nursery personnel [67].

### *Masks*

Nonsterile masks, face shields, goggles, and other eye protectors are worn in various combinations to provide barrier protection and should be used during procedures and patient care activities that are likely to generate splashes or sprays of body substances and fluids [23].

### *Other Standard Precautions*

Standard precautions also require that reusable patient care equipment be cleaned and appropriately reprocessed between patients; that soiled linen be handled carefully to prevent contamination of skin, clothing, or the environment; that sharps (i.e., needles, scalpels) be handled carefully to prevent exposure to blood-borne pathogens; and that mouthpieces and other resuscitation devices be used rather than mouth-to-mouth methods of resuscitation [23].

## Transmission-Based Precautions

In addition to standard precautions, which must be used for every patient, the CDC recommends transmission-based precautions when the patient is known or suspected to be infected or colonized with epidemiologically important or highly transmissible organisms. Always used in addition to standard precautions, transmission-based precautions comprise three categories: contact precautions, droplet precautions, and airborne precautions.

### *Contact Precautions*

Contact precautions involve the use of barriers to prevent transmission of organisms by direct or indirect contact with the patient or contaminated objects in the patient's immediate environment [23]. Sources of indirect contact transmission in nurseries include monitor leads, thermometers, isolettes, breast pumps [227], toys, and contaminated hands [208].

Ideally, a patient requiring contact precautions should be placed in a private room. Many nurseries have few if any isolation rooms, however. Cohorting of patients infected with the same microorganism can be a safe and effective alternative [23]. The American Academy of Pediatrics states that infected neonates requiring contact precautions can be safely cared for without an isolation room if staffing is adequate to allow appropriate hand hygiene, a 4- to 6-foot-wide space can be provided between care stations, adequate hand hygiene facilities are available, and staff members are well trained regarding infection transmission modes [67].

Health care workers should wear clean, nonsterile gloves when entering the room or space of a patient requiring contact precautions and should wear a cover gown when their clothing will have contact with the infant, environmental surfaces, or items in the infant's area. A cover gown also should be worn when the infant has excretions or secretions that are not well contained, such as diarrhea or wound drainage, which may escape the diaper or dressing. Infant care equipment should be dedicated to the patient if possible so that it is not shared with others [23]. Examples of conditions in the neonate that require contact precautions include neonatal mucocutaneous HSV infection, respiratory syncytial virus infection, varicella (also see airborne precautions), and infection or colonization with a resistant organism such as MRSA.

### *Droplet Precautions*

Droplet precautions are intended to reduce the risk of transmission of infectious agents in large-particle droplets from an infected person. Such transmission usually occurs when the infected person generates droplets during coughing, sneezing, or talking or during procedures such as suctioning. These relatively large droplets travel only short distances and do not remain suspended in the air and can be deposited on the conjunctiva, nasal mucosa, or mouth of persons working within 3 feet of the infected patient [23]. Patients requiring droplet precautions should be placed in private rooms (see earlier discussion of isolation rooms in nurseries in the section on contact precautions), and staff should wear masks when working within 3 feet of the patient [23]. Examples of conditions in the

neonate that necessitate droplet precautions are pertussis and invasive *Neisseria meningitidis* infection.

### Airborne Precautions

Airborne precautions are designed to reduce the risk of airborne transmission of infectious agents [23]. Because of their small size, airborne droplet nuclei and dust particles containing infectious agents or spores can be widely spread on air currents or through ventilation systems and inhaled by or deposited on susceptible hosts. Special air-handling systems and ventilation are required to prevent transmission. Patients requiring airborne precautions should be placed in private rooms in negative air-pressure ventilation with 6 to 12 air changes per hour. Air should be externally exhausted or subjected to high-efficiency particulate air (HEPA) filtration if it is recirculated [208].

Examples of conditions in neonates for which airborne precautions are required are varicella-zoster virus infections and measles. Susceptible health care workers should not enter the rooms of patients with these viral infections. If assignment cannot be avoided, susceptible staff members should wear masks to deliver care. If immunity has been documented, staff members need not wear masks [208]. Airborne precautions also are required for active pulmonary tuberculosis, and although neonates are rarely contagious, the CDC recommends isolating patients while they are being evaluated [228]. A more important consideration is the need to isolate the family of a suspected tuberculosis patient until an evaluation for pulmonary tuberculosis has been completed because the source of infection frequently is a member of the child's family [229,230].

# OTHER RELATED ISSUES

## HEALTH CARE WORKERS

Health care workers caring for neonates have the potential to transmit or to acquire infections while providing care to infant patients. Health care workers are at high risk of acquiring respiratory syncytial virus when caring for infected children and can subsequently spread infection to other patients [231–233]. Generally, health care workers with respiratory, cutaneous, mucocutaneous, or gastrointestinal infections should not deliver direct patient care to neonates [234]. In addition, nonimmune staff members exposed to highly communicable diseases, such as varicella and measles, should not work during the contagious portion of the incubation period [235]. In contrast, staff members with HSV infection rarely have been implicated in transmission of HSV to infants and do not need to be routinely excluded from direct patient care. Lesions should be covered, and health care workers should be instructed not to touch their lesions and to practice excellent hand hygiene.

Acquisition of CMV often is a concern of pregnant health care workers because of the potential effect on the fetus. The prevalence of asymptomatic CMV secretion is approximately 1% among infants in most nurseries [208]. Because the risk of acquiring CMV infection is the same for health care workers compared with the general population, pregnant caregivers can safely provide care to neonates who are shedding CMV.

Nurse-to-patient ratios have been inversely correlated with the rates of nosocomial infections and mortality [42,236,237]. Although optimal staffing ratios have not been established for NICUs and vary according to characteristics of individual units and patients, one study showed that the incidence of clustered *S. aureus* infections was 16 times higher after periods when the infant-to-nurse ratio exceeded 7:1. Decreased compliance with hand hygiene during a period of understaffing has been associated with increased rates of nosocomial infection [75].

## FAMILY-CENTERED CARE

Family-centered care has emerged as a guiding principle of pediatric health care. In the NICU, health care workers often encourage parents to become involved in the nonmedical aspects of their infant's care. Principles of family-centered care also include liberal NICU visitation for relatives, siblings, and family friends and the involvement of parents in the development of nursery policies and programs that promote parenting skills [238]. The benefits of family-centered care can be undermined by an increased risk of infection for the neonatal patient. Mothers can transmit infections to neonates postpartum, although separation of mother and newborn rarely is indicated. To ensure the risk of postpartum transmission is minimal, all mothers should wash their hands before handing their infants. For mothers with postpartum fever, care should be taken to ensure that the infant does not come into contact with contaminated dressings, linen, clothing, or pads [234].

Mothers with other infections can also safely visit their infants. Mothers with active herpes labialis should not kiss or nuzzle their infants until lesions have cleared; lesions should be covered, and a surgical mask may be worn until the lesions are crusted and dry. The importance of hand hygiene should be emphasized. Mothers with viral respiratory infections should be educated about how to interrupt transmission of these pathogens. Strategies such as covering a cough, prompt disposal of used tissues, and scrupulous hand hygiene should be taught before visiting. In addition, masks can be worn to reduce the risk of droplet transmission [234,235].

As previously mentioned, a few infections do require brief separations of mother and infant. Women with untreated active pulmonary tuberculosis should be separated from their infants until they no longer are contagious. Mothers with group A streptococcal infections, especially if a draining wound is present, also should be isolated from their infants until they are no longer contagious.

## BREAST-FEEDING

Numerous studies support the value of human milk for infants (see Chapter 5). Breast milk provides optimal nutritional content for infants, and breast-fed infants experience fewer episodes of infection and sepsis during the 1st year of life [15,239]. There are, however, several infectious contraindications to breast-feeding; mothers who have active untreated tuberculosis, human immunodeficiency virus (HIV) infection (except in countries where the risk of not breast-feeding outweighs the potential risk of HIV transmission [see Chapters 5 and 21]), breast abscesses

(as opposed to simple mastitis that is being treated with antimicrobial therapy), or HSV lesions around the nipples should not breast-feed. In contrast, mothers who are positive for hepatitis B surface antigen may safely breast-feed their infants because ingestion of infected milk has not been shown to increase the risk of transmission to an infant who has received hepatitis B virus immunoglobulin and vaccine immediately after birth [240].

Transmission of CMV has been observed in preterm infants who receive breast milk of CMV-seropositive mothers, presumably owing to the infant's low titers of anti-CMV antibody. Decisions regarding breast-feeding should weigh the benefits of human milk and the risk of CMV transmission. Freezing breast milk has been shown to decrease viral titers, but does not eliminate CMV; pasteurization of human milk can inactivate CMV (see Chapter 5). Either method may be considered in attempts to decrease risk of transmission for breast-feeding NICU neonates [241].

Neonates in the NICU frequently are incapable of breast-feeding because of maternal separation, unstable respiratory status, and immaturity of the sucking reflex. For these reasons, mothers of such infants must use a breast pump to collect milk for administration through a feeding tube. Pumping, collection, and storage of breast milk create opportunities for contamination of the milk and for cross-infection if equipment is shared among mothers. Several studies have shown contamination of breast pumps, contamination of expressed milk that had been frozen and thawed, and higher levels of stool colonization with aerobic bacteria in infants fed precollected breast milk [15,179,242,243]. Mothers who are able to pump or express their breast milk should be taught optimal collection, storage, and administration techniques. Cleaning and disinfection of breast pumps should be included in educational material provided to nursing mothers. In addition, mothers should be instructed to perform hand hygiene and cleanse nipples with cotton and plain water before expressing milk in sterile containers [211,241].

Expressed breast milk can be refrigerated for 48 hours and can be safely frozen ($-20°$ C $\pm$ 2° C [$-4°$ F $\pm$ 3.6° F]) for 6 months [211]. Vessels containing frozen breast milk can be thawed quickly under warm running water (avoiding contamination with tap water) or gradually in a refrigerator. Exposure to high temperatures, as may be experienced in a microwave, can destroy valuable components of the milk. Thawed breast milk can be stored in the refrigerator for 24 hours before it must be discarded. To avoid proliferation of microorganisms, milk administered through a feeding tube by continuous infusion should hang no longer than 4 to 6 hours before replacement of the milk, container, and tubing [234].

## VISITORS

The principles of family-centered care encourage liberal visitation policies in the well-infant nursery (or rooming-in scenario) and in the NICU. Parents, including fathers, should be allowed unlimited visitation to their newborns, and siblings should be allowed liberal visitation. Expanding the number of visitors to neonates may increase the risk of disease exposure, however, if education and screening for symptoms of infection are not implemented. Written policies should be in place to guide sibling visits, and parents should be encouraged to share the responsibility of protecting their newborn from contagious illnesses.

Adult visitors to neonates, including parents, have been implicated in outbreaks of infections including *P. aeruginosa* infection, pertussis, and *Salmonella* infection [236,244,245]. The principles for sibling visitation should be applied to adult visitors as well. Visitors should be screened for symptoms of contagious illness, should be instructed to perform hand hygiene before entering the NICU and before and after touching the neonate, and should interact only with the family member they came to the hospital to visit. Families of neonates who have lengthy NICU stays may come to know each other well and serve as sources of emotional support to one another. Nevertheless, they should be educated about the potential of transmitting microorganisms and infections between families if standard precautions and physical separation are not maintained, even though they may be sharing an inpatient space.

## SKIN AND CORD CARE

Bathing the newborn is standard practice in nurseries, but very little standardization in frequency or cleansing product exists. If not performed carefully, bathing can be detrimental to the infant, resulting in hypothermia, increased crying with resulting increases in oxygen consumption, respiratory distress, and instability of vital signs [177]. Although the initial bath or cleansing should be delayed until the neonate's temperature has been stable for several hours, removing blood and drying the skin immediately after delivery may remove potentially infectious microorganisms such as hepatitis B virus, HSV, and HIV, minimizing risk to the neonate from maternal infection [234]. When the newborn requires an intramuscular injection in the delivery room, infection sites should be cleansed with alcohol to prevent transmission of organisms that may be present in maternal blood and body fluids [170]. For routine bathing in the first few weeks of life, plain warm water should be used. This is especially important for preterm infants and full-term infants with barrier compromise such as abrasions or dermatitis. If a soap is necessary for heavily soiled areas, a mild pH-neutral product without additives should be used, and duration of soaping should be restricted to less than 5 minutes no more than three times per week [177].

Few randomized studies comparing cord care regimens and infection rates have been performed, and consensus has not been reached on best practice regarding care of the umbilical cord stump. A review published in 2003 described care regimens used for more than 2 decades, including combinations of triple dye, chlorhexidine, 70% alcohol, bacitracin, hexachlorophene, povidone-iodine, and "dry care" (soap and water cleansing of soiled periumbilical skin), and found variable impact on colonization of the stump [246]. The study authors suggested that dry cord care alone may be insufficient and that chlorhexidine seemed to be a favorable antiseptic choice for cord care because of its activity against gram-positive and gram-negative bacteria. They went on to stress, however, that

large, well-designed studies were required before firm conclusions could be drawn. The current Perinatal Guidelines do not recommend a specific regimen, but warn that use of alcohol alone is not an effective method of preventing umbilical cord colonization and omphalitis [241]. The Perinatal Guidelines further recommend that diapers be folded away from and below the stump and that emollients not be applied to the stump [177].

# Laboratory Aids for Diagnosis of Neonatal Sepsis

Geoffrey A. Weinberg ◎ Carl T. D'Angio

CHAPTER OUTLINE

For years, investigators have sought a test or panel of tests able to diagnose neonatal sepsis accurately and more rapidly than is possible with the isolation of microorganisms from specimens of sterile body fluids or tissues. Although results of some studies have been encouraging, the isolation of microorganisms from sources such as the blood, cerebrospinal fluid (CSF), urine, other body fluids (peritoneal, pleural, joint, middle ear), or tissues (bone marrow, liver, spleen) remains the most valid method of diagnosing bacterial sepsis. Many advances in non–culture-based methods, which may nevertheless remain microorganism specific, such as tests employing polymerase chain reaction (PCR) amplification technology, are promising for more rapid diagnosis of infection. This chapter discusses nonspecific laboratory aids for the diagnosis of invasive bacterial infections. Specific microbiologic techniques are discussed in Chapter 6 and in chapters addressing specific pathogens.

## DIAGNOSTIC UTILITY OF LABORATORY TESTS

In establishing the usefulness of any laboratory determination, a balance must be reached between sensitivity and specificity [1]. For a clinician needing to decide whether to institute or withhold therapy on the basis of a test result, the predictive values (and perhaps likelihood ratios) [2] of that test are also important. In relation to neonatal infection, these terms can be defined as follows (Fig. 36–1):

*Sensitivity*: If infection is present, how often is the test result abnormal?
*Specificity*: If infection is absent, how often is the test result normal?
*Positive predictive value*: If the test result is abnormal, how often is infection present?
*Negative predictive value*: If the test result is normal, how often is infection absent?
*Likelihood ratio, positive test result*: If the test result is abnormal, how much does that result increase the pretest probability of disease?
*Likelihood ratio, negative test result*: If the test result is normal, how much does that result decrease the pretest probability of disease?

In attempting to discover the presence of a serious illness such as neonatal bacteremia, which is life-threatening yet treatable, diagnostic tests with maximal (100%) sensitivity and negative predictive value are desirable. In other words, if infection were present, the result would always be abnormal; if the result were normal, infection would always be absent. The reduced specificity and positive predictive value that this combination may engender usually are acceptable because overtreatment with antibiotics on the basis of a false-positive result is likely to be of limited harm compared with withholding therapy on the basis of a false-negative result. Some authorities prefer the use of likelihood ratios because predictive values vary with the prevalence of a disease, while likelihood ratios relate only to the test performance (sensitivity, specificity) [3,4]. Large likelihood ratios ($>$10) imply that a test result would conclusively increase the probability of the disease being present, whereas small likelihood ratios ($<$0.1) minimize the probability of the disease being present.

In reviewing a report of a new laboratory aid for the diagnosis of neonatal sepsis, the first consideration is to determine what reference standard was used to evaluate the new test (i.e., what was the gold standard applied). In one study of infants who died with unequivocal

evidence of infection at autopsy, bacteria were grown from 32 of 39 antemortem blood cultures (sensitivity of only 82%) [5]. Among 50 infants without pathologic findings of infection at autopsy, 48 had negative blood culture results (specificity of 96%). A positive blood or CSF culture result had a 94% chance of being associated with serious neonatal infection (positive predictive value of 94%), whereas a negative blood culture result indicated absence of serious infection only 87% of the time (negative predictive value of 87%). It is likely that the predictive values cited in this study already are different from the values that may be observed in practice because of the high prevalence (44%) of positive bacterial culture results in the autopsy cases reviewed [5]. (High prevalence inflates the positive predictive value and depresses the negative predictive value; low prevalence depresses the positive predictive value and inflates the negative predictive value.)

The lack of perfection of the generally accepted gold standard of bacterial culture complicates the search for new laboratory aids in the diagnosis of neonatal sepsis; it may be unclear whether a new test is truly functioning better than culture, which itself may not be "perfect." Interpretation of bacterial culture results may become even more complicated as intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal sepsis becomes more common [6–9]. It may not be clinically necessary to require detection of only *bacterial* sepsis. Tests that yield results considered "falsely positive" in the absence of bacterial disease may still be clinically useful in assigning normal versus abnormal status if the results register positive because of *serious viral disease* that may require antiviral therapy (e.g., neonatal enterovirus or herpes simplex infections).

Two additional points warrant consideration in this context. First, unless the report is generated from an unselected cohort or prospective study, the predictive values given in the report may be misleading. Prevalence of sepsis may vary greatly if certain groups of newborns are preselected, which would alter the predictive values of the test being studied. The most useful test in one population of infants with very low birth weight may function quite differently in another population of older infants with larger birth weights who are growing normally. Second, because the body's response to an infection necessarily begins after the invasion of a pathogen, it may never be possible to diagnose an infection immediately—there may always be a lag in the physiologic response on which the diagnostic test is based. Each report of a new test claiming superiority to bacterial culture must be critically evaluated in the extended clinical setting, and standardization within clinical laboratories and among institutions is required.

## IN SEARCH OF THE IDEAL LABORATORY TEST

Even bacterial blood cultures performed with modern, continuously computer-monitored detection technology do not reach 100% sensitivity for the diagnosis of neonatal infection. Incubation of bacteria may take several days, and genuine bacteremia may be missed because of the small volume of blood taken from infants with very low birth weight. A set of properties of the ideal or perfect diagnostic test has been proposed [10,11]. These characteristics should be kept in mind as the different laboratory tests for neonatal infection are discussed in this chapter.

First, the laboratory analyte would be biochemically stable (to ease transport requirements), easy to analyze (quick laboratory turnaround time), and obtainable from a small volume of blood. Second, the analyte would have clear diagnostic cutoffs between normal and abnormal, across various gestational ages, and across birth weights. Third, the test would be inexpensive and comparable among different laboratories, so that it could be widely applied.

In addition, the ideal laboratory test for the diagnosis of neonatal infection would be maximally sensitive (no false-negative results) and highly specific (few false-positive

results) and have a physiologic window of opportunity for sampling. More precisely, the test would become abnormal just as infection was present and remain abnormal for some time, to allow for clinicians to use it as a diagnostic aid even if the clinical symptoms of infection were initially missed.

Finally, the ideal marker would correlate well with progress of infection, perhaps even predicting outcome [10,11]. As we review each test in this chapter, it will become apparent that none of the currently available laboratory aids for the diagnosis of infection fulfill these ideal properties. Although new tests are continually being studied, it is uncertain that any will ever achieve perfection.

## COMPLETE BLOOD COUNTS AND WHITE BLOOD CELL RATIOS

### TOTAL LEUKOCYTE COUNT, DIFFERENTIAL LEUKOCYTE COUNT, AND MORPHOLOGY

Total leukocyte counts are of limited value in the diagnosis of septicemia in newborns [12–16]. Total leukocyte counts are particularly unreliable indicators of infection during the first several hours of early-onset (within 48 hours of birth) sepsis because they are normal at the time of initial evaluation in more than one third of infants with proven bacteremia [5,17–28]. Conversely, among neonates evaluated for suspected sepsis, far less than half of neonates with reduced (<5000 cells/$mm^3$) or elevated (>20,000 cells/$mm^3$) cell counts are ultimately identified to be infected [5,20,22,29].

Differential leukocyte counts also have not functioned well as markers for infectious disease in the newborn period. Increased percentages of lymphocytes have been described in association with pertussis and congenital syphilis, whereas minor changes of little diagnostic value have been noted in infants with ABO incompatibility, in sepsis, and in maternal hypertension [30,31]. Monocyte counts, normally higher in neonates than in older children or adults, may be elevated further in some cases of congenital syphilis, perinatal listeriosis, ABO incompatibility, and recovery from sepsis [27,31–36]. Eosinophilia, a common finding in premature infants, has been related to numerous factors, including low birth weight, immaturity, establishment of positive nitrogen balance, improved nutritional status, and use of total parenteral nutrition or blood transfusions [36–41]. A dramatic decrease in the absolute number of eosinophils, detectable only if serial counts have been performed, frequently accompanies sepsis or serious infection [31,38,42]. Basophil counts tend to follow the fluctuations in eosinophil numbers in ill or healthy newborns [40]. Conflicting data have been reported for the utility of differential leukocyte counts for identifying neonates with bacterial meningitis [43,44].

Several investigators have shown that significant changes in neutrophil morphology occur in association with serious bacterial infection, with the appearance of toxic granules, Döhle bodies, and vacuolization [25,42–47]. These features are of limited value in establishing a diagnosis; their presence has at best a positive predictive value for sepsis of only slightly more than 50% [5,25,45–47] and at worst a positive predictive value of 33% to 37% [48,49]. Identical morphologic features can occur as artifacts in citrate-anticoagulated blood samples stored for longer than 1 hour before smears are made [50].

### TOTAL NEUTROPHIL COUNT

Recognizing the low predictive value of total leukocyte counts in serious neonatal bacterial disease, several investigators have studied the dynamics of neutrophil counts during the 1st month of life [35,42,45,51–56]. These researchers and others uncovered patterns of change sufficiently constant to establish limits of normal variation (Fig. 36–2) and defined noninfectious conditions involving the mother or the infant that might have significant effects on neutrophil values (Tables 36–1 and 36–2). Largely on the basis of these data, it was suggested that calculation of the absolute number of circulating neutrophils (polymorphonuclear plus immature forms) might provide a useful index of neonatal infection. Clinical experience has only partly supported this premise.

Most series of consecutive cases of neonatal sepsis have shown abnormal neutrophil counts at the *time of onset of symptoms* in only about two thirds of infants.* In some series, 80% to 90% of infected infants have had abnormal values [23,48,51,71], whereas in other series, initial neutrophil counts were reduced or elevated in only one fourth to one third of infants with bacteremia, particularly when counts were determined early in the course of illness [28,57,72]. The neutrophil count, although slightly more sensitive than the total leukocyte count, is too often normal in the face of serious infection to be used as a guide for treatment.

Baley and associates [52] investigated the causes of neutropenia among consecutive admissions to a neonatal intensive care unit. Low neutrophil counts were found in 6% of these infants, most of whom were premature and of low birth weight. Less than half of the episodes of neutropenia could be attributed to infection (bacterial, viral, necrotizing enterocolitis). Rather, most were of unknown cause or occurred in infants with perinatal complications. Similar findings have been described by Rodwell and coworkers [59] among 1000 infants evaluated for sepsis in the first 24 hours of life.

The neutrophil count can be of value in specific clinical situations. The association of neutropenia, respiratory distress, and early-onset (<48 hours) sepsis caused by group B streptococci is well documented [18,23,63,73–76], although the recognition that a similar association exists for early sepsis caused by other microorganisms has not been adequately emphasized. Several authors have described infants with septicemia related to *Haemophilus influenzae* [77,78], pneumococci [79–81], *Escherichia coli* [78], or nonenterococcal group D streptococci [82] whose clinical course was similar to that described for group B streptococcal infection. Because all infants were noted to be ill at birth or shortly thereafter, when neutrophil counts normally are increasing, a low count (0 to 4000 cells/$mm^3$) in this clinical setting is a highly significant finding. In many cases, the low number of circulating neutrophils reflects a depletion of bone marrow

granulocyte reserves [78,83] and usually indicates a poor prognosis.* The absolute neutrophil count may be useful for screening infants with symptomatic illness including respiratory distress in the first few hours of life, if not for asymptomatic infants [29,85].

## TOTAL NONSEGMENTED NEUTROPHIL COUNT

The blood smear and differential cell count during the newborn period are strikingly different from values seen at any other time of life. Immature forms are present in relatively large numbers, particularly among premature infants and during the first few days of life [35,45,46,86]. The number of immature neutrophils, mostly nonsegmented (band, stab) forms, increases from a maximal normal value of 1100 cells/mm$^3$ in cord blood to 1500 cells/mm$^3$ at 12 hours of life and gradually decreases to 600 cells/mm$^3$ by 60 hours of life. Between 60 and 120 hours, the maximum count decreases from 600 to 500 cells/mm$^3$ and remains unchanged through the 1st month of life [45]. For unexplained reasons, possibly related to differences in the definition of a nonsegmented neutrophil [65], higher counts have been recorded by other authors [16,61]. Metamyelocytes and myelocytes also are often present in significant numbers during the first 72 hours after delivery, but disappear almost entirely toward the end of the 1st week of life [35]. Even occasional promyelocytes and blast cells may be seen during the early days of life in healthy infants [35].

As neutrophils are released from the bone marrow in response to infection, an increasing number of immature cells enter the bloodstream, producing a differential cell count with a "shift to the left" even greater than that normally present in the neonate [71]. This response is so inconstant, however, that, with few exceptions [18,65,66], the absolute band or immature (bands, metamyelocytes) neutrophil count has been found to be of little diagnostic value.* In many infants with infection, despite an increased proportion of immature cell types in the differential leukocyte count, exhaustion of the bone marrow reserves prevents an increase in the absolute number of band neutrophils in the circulation [83,87,88]. This is particularly common in more seriously ill patients, in whom early diagnosis is most critical [5,71,78,83].

Despite its relative insensitivity, the immature neutrophil count has been found to have good positive predictive value in some [5,46,49,71,75], although not all [48], studies. In infants with clinical evidence of sepsis and high band counts in whom culture results remain negative, follow-up cultures and investigation for a history of perinatal events that might explain the discrepancy (see Table 36–1) or for the possibility of infection related to other causes, such as enteroviruses, are indicated [89].

## NEUTROPHIL RATIOS

The unreliability of absolute band counts led to the investigation of neutrophil ratios as an index of neonatal infection. Determinations have included the ratio of either bands or all immature neutrophils (e.g., bands, metamyelocytes, and myelocytes) to either segmented neutrophils (the immature-to-mature neutrophil ratio [I:M ratio]) or to all neutrophils (the immature-to-total neutrophil ratio [I:T ratio]). Despite the early enthusiasm of researchers, the clinical studies that include these determinations have failed to show a consistent correlation with the presence of serious bacterial disease. As might be expected, low band counts caused by exhaustion of marrow can produce misleadingly low ratios in the presence of serious or overwhelming infection [46,75,82,83].

Clinical experience with I:M ratios [46,71] is insufficient to verify their accuracy. Initial studies in which the I:M ratio was used have been disappointing, however, with normal values recorded in more than one third of infected infants. Band-to-total neutrophil ratios, although more extensively studied, also have proved to be too unpredictable to be diagnostically helpful. The most favorable report would have missed 10% of neonates with sepsis, while recording falsely abnormal values in almost 20% of uninfected infants [20]. The sensitivity of this determination in other series varies, ranging from 70% to 30%, which precludes its use in a clinical setting [24–26,70,71].

The I:T ratio is the best studied of the ratios [70,90]. Inclusion in the numerator of all immature forms, rather than just band cells, heightens accuracy by accounting for the increase in metamyelocytes that is sometimes seen with accelerated release from the neutrophil storage pool [71]. Use of total rather than segmented neutrophils in the denominator has the advantage of always yielding a value between 0 and 1 inclusive. The maximum ratio for the first 24 hours is 0.16 [45,60]. It gradually declines to around 0.12 by 60 hours of age and remains unchanged for the remainder of the 1st month [45]. A normal value up to 0.2, with age unspecified, has been found in some laboratories [20]. I:T ratios during the first 5 days of life

*References [5,18,26,42,78,84].

*References [5,26,48,57,63,72,74,75].

are less than 0.2 in 96% of healthy premature infants with a gestational age of 32 weeks or less [86].

Numerous clinical studies have evaluated the I:T ratio. Results have been widely disparate, but in most series, they indicate that this ratio is too unreliable to achieve more than limited usefulness by itself. Sensitivities ranging from more than 90%* to 70% [22,92], 60% [57,69,72], or less [93,94] have been reported. Elevated ratios caused by various perinatal conditions have been seen in 25% to 50% of uninfected ill infants (see Table 36–1) [21,22]. Perhaps the greatest value of the I:T ratio lies in its good negative predictive value: If the I:T ratio is normal, the likelihood that infection is absent is extremely high (99%).†

Serial determinations of the I:T ratio may lead to increased sensitivity [49,90,95]. Some authors have found, however, that interreader variability leads to enough bias to limit the usefulness of leukocyte ratios for general use [96].

## PLATELET COUNT

Several extensive studies have established that the normal platelet count in newborns, regardless of birth weight, is rarely less than 100,000/mm$^3$ during the first 10 days of life or less than 150,000/mm$^3$ during the next 3 weeks [18,69,97–100]. Although it would behoove the clinician to perform a work-up for sepsis in any infant with unexplained thrombocytopenia [100–102], a reduction in the number of circulating platelets has been shown to be an insensitive, nonspecific, and relatively late indicator of serious bacterial infection during the neonatal period. Automated measurements of mean platelet volume have added little to the platelet count as a diagnostic aid [103,104].

Only 10% to 60% of newborns with proven bacterial invasion of the bloodstream or meninges have platelet counts of less than 100,000/mm$^3$.* The average duration of thrombocytopenia is about 1 week, but can be 2 to 3 weeks. The nature of the organism involved (whether gram-positive, gram-negative, or fungal) has been reported in some, but not all, studies to correlate with the platelet count nadir and duration of thrombocytopenia [18,72,99,103]. Although platelet counts may begin to decrease several days before the onset of clinical signs of infection, in most cases values remain elevated until 1 to 3 days after serious illness is already apparent [19,26,41,65,99]. Thrombocytopenia accompanying bacterial infection is thought to be caused by a direct effect of bacteria or bacterial products on platelets and vascular endothelium, leading to increased aggregation and adhesion, or by increased platelet destruction caused by immune mechanisms [46,65,99–101].

In addition to the widely known association between thrombocytopenia and intrauterine infections related to syphilis, toxoplasmosis, rubella, and cytomegalovirus infection, reduced platelet counts also have been described with postnatal viral infections with enteroviruses and herpes simplex virus, each of which can cause an illness clinically indistinguishable from bacterial sepsis [101–106]. Conditions that predispose the infant to sepsis, such as placement of an umbilical catheter, birth asphyxia, mechanical ventilation, meconium aspiration, multiple exchange transfusions, and necrotizing enterocolitis, have independently caused thrombocytopenia in the absence of positive blood culture results [41,102,107–109]. Nonspecific neonatal thrombocytopenia also has been reported with various conditions causing maternal thrombocytopenia, including pregnancy-induced hypertension [41]. Infants with moderate to severe Rh hemolytic disease also are thrombocytopenic [110].

## ACUTE PHASE REACTANTS

In the presence of inflammation caused by infection, trauma, or other cellular destruction, the liver, under the influence of proinflammatory cytokines interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α, rapidly synthesizes large amounts of certain proteins collectively known as *acute phase reactants* [111–114]. Serum levels of these proteins usually increase together, and generally the degree of change in one is proportional to the degree of change in the others (two important exceptions are albumin and transferrin, which decrease together) (Fig. 36–3). Acute phase reactants are produced very early in fetal life, beginning in the 4th to 5th week of gestation [115]. Their exact role in the inflammatory process is unknown; most seem to be part of a primitive nonspecific (innate) defense mechanism. Several acute phase reactants have been extensively evaluated in neonatal sepsis, including C-reactive protein (CRP), fibrinogen, and other proteins that influence the erythrocyte sedimentation rate; haptoglobin; and $\alpha_1$-acid glycoprotein (orosomucoid). Measurement of proinflammatory cytokines and their receptors, chemokines, cell markers, and anti-inflammatory cytokines also

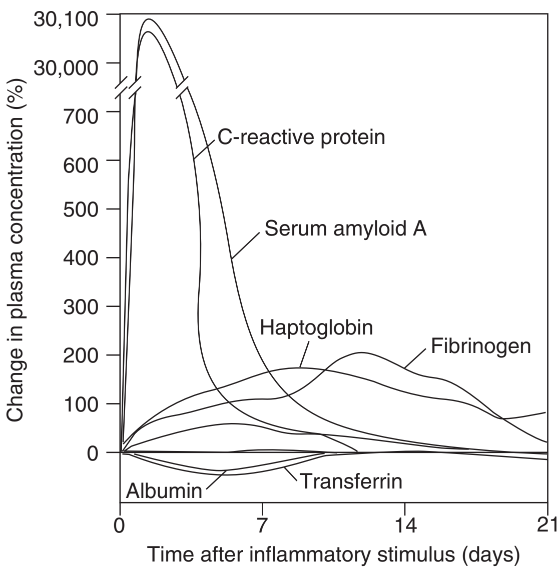

**FIGURE 36–3 Acute phase reactants in patients with inflammatory illnesses.** The response of C-reactive protein is greater than that of all other acute phase proteins except serum amyloid A. Levels of certain plasma proteins decrease during the acute phase response. *(Data from Gabay C, Kushner I. Acute-phase proteins and other systemic responses to inflammation. N Engl J Med 340:448–454, 1999.)*

*References [17–19,23,25,48,72,99].

involved in the immune cascade following infection holds promise to increase diagnostic accuracy further; these tests are discussed later.

## C-REACTIVE PROTEIN

The most useful of the acute phase reactants seems to be CRP. CRP is a globulin that forms a precipitate when combined with the C-polysaccharide of *Streptococcus pneumoniae* [113,114]. Because the appearance of CRP in the blood has been closely associated with tissue injury, particularly when caused by an acute inflammatory process, it has been suggested that the primary function of CRP is to act as a carrier protein, binding and facilitating clearance of potentially toxic foreign or altered materials released from invading microorganisms or damaged tissues. Its roles in activation of the classic complement pathway, promotion of phagocytosis, regulation of lymphocyte function, and platelet activation are unclear [70,111–114].

Differences in laboratory techniques and in the interpretation of what constitutes a positive result for CRP assay have been partly responsible for conflicting opinions about the reliability of this test during the neonatal period [70,113,116,117]. Early clinical reports must be interpreted in light of the knowledge that the capillary tube precipitation and gel immunodiffusion techniques used for assay of CRP in those studies were less sensitive and specific than more modern immunochemical methods [70,117]. A comparison of reactions obtained by different investigators using the capillary tube method revealed widely disparate results, depending on the sensitivity of the commercial antiserum used in the assay.

Newer rapid and reliable quantitative methods have been developed in which monoclonal CRP-specific antibody is used [117–120]. Fully automated turbidimetric and nephelometric methods can provide quantitative results in 30 to 60 minutes, whereas enzyme immunoassays, such as the enzyme-multiplied immunoassay technique, can give results in less than 10 minutes. Determination of CRP levels in serum by numerous authors using many techniques (radial immunodiffusion, electroimmunodiffusion, spot immunoprecipitate assay, enzyme-multiplied immunoassay technique, and nephelometry) has shown the upper limit of normal to be 10 mg/L (1 mg/dL) during the neonatal period [49,113,114,118,121]. Analysis of paired serum specimens obtained from mothers and their infants (fetuses and premature infants and full-term neonates) has shown that CRP crosses the placenta either only in very low concentrations or not at all [113]. Gestational age does not seem to influence the validity of results [23,113]. CRP normal ranges may vary with time over the first 48 hours of life, however, with 95th percentile values of 5 mg/dL, 14 mg/dL, and 10 mg/dL at 0, 24, and 48 hours of age [117,122].

Most surveys in sera of neonates with systemic bacterial infections have shown significant elevations of CRP levels *at the time of onset of signs* (i.e., diagnostic test sensitivity) in 50% to 90% of cases.* A poor response is particularly frequent among infants whose infection occurs during the first 12 to 24 hours of life and among infants with infection caused by gram-positive bacteria, including group B streptococci [23,91,124]. Although the intensity of the response does not always reflect the severity of the infection, the relationship between formation of CRP and the degree of tissue injury indicates that infants who show a positive response usually have systemic infections or involvement of deeper tissues [23,130].

Measurement of CRP levels is not completely specific. The response of CRP to nonbacterial infections is variable; increased serum levels have been found in infants with viral infections [131]. A strong correlation between elevated CRP levels and chorioamnionitis has been described in women with premature rupture of membranes and in the cord blood of their infants [132,133]. Increases of CRP levels in neonates also have been associated with noninfectious conditions causing tissue injury or inflammation, such as fetal asphyxia, respiratory distress syndrome, intracerebral hemorrhage, and meconium aspiration pneumonitis [121,124,134]. Because these conditions often are confused or associated with newborn bacterial infection, such false-positive elevations greatly reduce the positive predictive value of CRP determinations and their usefulness in diagnosis. The mean incidence of falsely elevated CRP values in ill but not septic neonates is approximately 5% to 15% [91,94,123,134,135].

The reported overall sensitivity of CRP at the onset of signs of sepsis ranges from 50% to 90%, and the specificity ranges from 85% to 95%. The positive and negative predictive values may range from 30% to greater than 95%. It is clear from the foregoing discussion that despite new technology permitting more rapid and precise measurement, reliance on CRP levels *alone* as an early indicator of neonatal bacterial infection cannot be recommended. Although CRP levels possibly are helpful in combination with other tests as part of a sepsis screening panel (see later discussion), when CRP assay is used alone as an initial test for infection, even if the most favorable results are assumed, approximately 10% of cases would be missed, and 5% of uninfected infants would be incorrectly diagnosed as having infection.

Nevertheless, determination of serial CRP levels does seem to be of some value in excluding serious infection [70,113,114,135]. Although assay results in a few infants are normal at the onset of invasive bacterial disease, CRP levels increase rapidly and usually are abnormal within 1 day (CRP doubling time is 8 hours). CRP levels peak at 2 to 3 days and remain elevated until infection is controlled and resolution of the inflammatory process begins [21,23,91,113,136]. Thereafter, by virtue of a relatively short serum half-life of about 19 hours, CRP levels decline promptly and return to normal within 5 to 10 days in most infants who have a favorable outcome [23,24,114,135].

Serial measurements of CRP levels over 1 to 3 days after onset of possible neonatal bacterial infection may help determine the duration of antibiotic therapy and identify the occurrence of relapse or complications during or after treatment of known infection. Several studies document that serial determination of CRP levels in this fashion yields diagnostic sensitivity of 75% to 98%; specificity of 90%; and, perhaps most notably, negative predictive value of 99% [49,124–127,135–138]. These studies suggest that although the relatively low sensitivity of initial CRP

*References [21,23,49,70,113,114,122–129].

determination precludes the firm diagnosis of bacterial infection, the very high negative predictive value of several normal CRP determinations in combination allows the early cessation of empirical 7- to 10-day courses of intravenous antibiotics. It is less likely, however, that serial CRP determinations would allow cessation of empirical 2- to 3-day courses of antibiotics. Also, the kinetics of increase and decrease of elevated CRP levels does not differ sufficiently to allow distinction between newborns with positive bacterial blood cultures and newborns with negative bacterial blood cultures [136].

## PROCALCITONIN

Several authors have described an early and specific elevation in serum levels of procalcitonin in infants with invasive bacterial disease [139–143]. Procalcitonin concentrations naturally fluctuate during the first 48 hours of life, however, mandating careful (perhaps hourly) adjustments in the normal reference ranges and complicating use of procalcitonin as a diagnostic aid [122,143–145]. In addition, the normal reference ranges seem to depend on the estimated gestational age of the premature newborn [146]. Elevation of procalcitonin levels was only modestly reliable (75% to 80% sensitivity and specificity) even for the diagnosis of late-onset sepsis in older neonates in whom the fluctuations after birth had resolved [147].

## ERYTHROCYTE SEDIMENTATION RATE

The development more than 50 years ago of an erythrocyte sedimentation rate, by use of a microhematocrit tube and a few drops of capillary blood, permitted the application of this test in very small infants [148,149]. Attempts at standardization have shown that the microerythrocyte sedimentation rate increases slowly during the first weeks of life, perhaps as a result of increasing fibrinogen and decreasing hematocrit levels. Maximal normal rates have varied so widely, however, that any laboratory attempting to use this test in neonates must establish its own normal values [150–152].

Sedimentation rates do not vary significantly with gestational age, birth weight, or gender, but are related inversely to the hematocrit level, particularly in infants with hematocrit readings of less than 0.40 [150,151]. Comparisons between the microerythrocyte sedimentation rate and standard methods have shown good correlation in simultaneous analyses of samples obtained from cord blood, from infants with physiologic jaundice, and from healthy older children [150]. Rapid alternative methods, such as determination of the zeta sedimentation ratio [153] and plasma viscosity [154], compared well with standard erythrocyte sedimentation rate assays and were thought to reflect a change in the same plasma proteins; however, they have not been evaluated in newborns. The microerythrocyte sedimentation rate generally is normal or only mildly elevated in noninfectious conditions, such as respiratory distress syndrome, aspiration pneumonia, and asphyxia, and in superficial infections [150,152]. Significant elevations are unusual in healthy infants, but can occur in the presence of Coombs-positive hemolytic disease and physiologic hyperbilirubinemia [21,150,152].

Although extensive clinical experience has shown that sedimentation rates eventually become elevated in most infants with systemic bacterial infections, this increase may not have occurred at the time of the initial evaluation in 30% to 70% of infants with proven sepsis, particularly when disseminated intravascular coagulopathy is present.* When the sedimentation rate is elevated, its return to normal can be exceedingly slow despite clinical recovery, sometimes taking several weeks from the time of onset of illness [150]. Use of the microerythrocyte sedimentation rate is of little value in either diagnosing or monitoring serious bacterial infection during the newborn period.

## OTHER ACUTE PHASE REACTANTS

### Fibrinogen

The increase in plasma fibrinogen level associated with infection has been recognized for many years through its effects on the erythrocyte sedimentation rate. Clinical experience with the use of fibrinogen levels is limited, but generally disappointing. Median fibrinogen concentrations in infected infants overlapped to a great extent with levels obtained from normal infants, and low values despite severe infection also have been reported [155,156]. Concentrations may be affected by birth weight and test methodology and decrease dramatically in the presence of disseminated intravascular coagulopathy.

### Haptoglobin

Haptoglobin is an $\alpha_2$-glycoprotein that reacts with free hemoglobin to form a complex, which is removed by the reticuloendothelial system. Gestational age, neonatal asphyxia, gender, and hemolytic ABO/Rh disease have no significant influence on haptoglobin levels in cord blood or during the postnatal period; however, elevated levels usually persist for several days after exchange transfusion, probably as a result of passive transfer of blood with adult concentrations of the protein. Inaccuracies related to phenotypic variants of haptoglobin, although seen when levels are measured by radial immunodiffusion, have not presented a problem when concentrations are determined by laser nephelometry. Clinical studies have raised serious doubts about the reliability of haptoglobin concentrations in the prediction of neonatal sepsis [20,24,121,157,158].

### $\alpha_1$-Acid Glycoprotein

$\alpha_1$-Acid glycoprotein (orosomucoid) is produced by lymphocytes, monocytes, neutrophils, and hepatocytes. It exists as an integral membrane protein of leukocytes and is liberated into the plasma as the cells disintegrate [112]. The function of $\alpha_1$-acid glycoprotein is unknown, but it may have a role in forming collagen, binding steroid hormones, and modifying lymphocyte responsiveness [138,159]. Although early studies suggested that $\alpha_1$-acid glycoprotein might be a specific and sensitive indicator

*References [21,23,84,128,150,152].

of neonatal bacterial infection, subsequent surveys have been unable to confirm this favorable experience [20,121,130,138,159–164].

### Others

Other acute phase proteins evaluated for the early diagnosis of neonatal sepsis include $\alpha_1$-proteinase inhibitor ($\alpha_1$-antitrypsin) [24,164], the complex of elastase and $\alpha_1$-proteinase inhibitor [165,166], $\alpha_1$-antichymotrypsin [164], inter-α-inhibitor proteins [167], ceruloplasmin [168], and secretory phospholipase $A_2$ [169]. No definitive clinical studies suggest that any of these reactants are helpful for diagnosis or management in the neonate suspected to have a bacterial infection. Serum amyloid A protein, another acute phase reactant, seemed to be slightly more sensitive than CRP in predicting early-onset sepsis in full-term infants, although the differences were not maintained after 24 hours of symptoms, and few normal controls were studied to define specificity [170].

## ADDITIONAL LABORATORY STUDIES

### CYTOKINES AND CHEMOKINES

Cytokines such as IL-1β, IL-6, IL-10, and TNF-α and chemokines such as IL-8 and others are endogenous mediators of the innate immune response to inflammation, including (but not limited to) inflammation caused by bacterial infections. Cord and postnatal blood cytokine concentrations may vary as a result of clinical complications during the perinatal period. IL-1β is elevated in cord plasma specimens from infants born after induced vaginal or urgent cesarean delivery, whereas IL-6 is elevated in the presence of chorioamnionitis and delivery room intubation, yet depressed in the presence of pregnancy-induced hypertension [123,171,172]. Because of the confounding effects of maternal complications, differences in chronologic age from the first hours to days of life, and illness severity, the reported performance of various cytokine markers must be viewed with some caution [4,117,123]. Also, it is not always clear that the first available laboratory method of measuring a cytokine is the most sensitive; it has been reported that the sensitivity and specificity of IL-8 assays are improved markedly by measuring detergent-lysed whole-blood samples, rather than by using plasma samples as reported in earlier studies [173].

Nevertheless, several studies suggest that elevated levels of IL-6 detected after birth may provide an early and sensitive parameter for the diagnosis of neonatal bacterial infection [121–123,172,174–179]. Elevated concentrations have also been correlated with a fatal outcome in older children [180]. Similarly, levels of IL-8 were found to be elevated in cord blood from infants in whom histologic evidence of chorioamnionitis was noted and in infants with sepsis [129,175,181,182]. Because of variations in study design and methodology, estimates of diagnostic sensitivity and specificity for IL-6 and IL-8 levels range from 60% to greater than 95% for each [129,183–185]. In addition, although plasma and tracheal aspirate IL-8 and IL-10 levels correlate with bacterial sepsis, they are nonspecific in neonates with necrotizing enterocolitis [186].

### ADHESION MOLECULES AND CELLULAR RECEPTORS

Upregulation of adhesion molecules such as E-selectin, L-selectin, and intercellular adhesion molecule-1 has been suggested as a discriminating feature of bacterial sepsis [125,178,187–189]. Genetic polymorphisms in mannose-binding lectins seem to underlie susceptibility to infection in some premature neonates; it is unknown whether this analyte could be used for diagnostic purposes [190]. Cytokine receptors and receptor antagonists such as soluble TNF-α and IL-2 receptors and IL-1 receptor antagonist have been explored as potential aids in the laboratory diagnosis of neonatal sepsis [129,176,183,191,192]. Further clinical data are needed to determine whether measurement of these analytes is truly useful for the diagnosis and follow-up evaluation of neonatal sepsis.

### LYMPHOCYTE AND NEUTROPHIL MARKER ANALYSIS

Another component of the inflammatory response to infection is the change in surface markers of white blood cell populations as measured by flow cytometry. Activation of T lymphocytes after infection results in upregulation of the lymphocyte surface marker CD45RO isoform coupled to loss of the CD45RA isoform. Sequential analysis of the distribution of early CD45RA-CD45RO dual expression and later CD45RO expression alone discriminated bacterial (and viral) infection from respiratory distress or erythrocyte incompatibility in a few infants [193]. The surface expression of the neutrophil surface marker CD11b yielded good sensitivity, specificity, and predictive values in diagnosing neonatal bacterial and fungal infection in several studies [188,194,195]. The expression of CD11b and other markers such as soluble CD40 ligand may be affected by duration of labor and chronologic age; further studies are required to define normal ranges and clinical utility [188,196,197]. Expression of another neutrophil surface marker, CD64, has been found to correlate with early-onset and late-onset nosocomial newborn sepsis in some studies [198–200].

### MISCELLANEOUS ANALYTES

Fibronectin is an adhesive, high-molecular-weight glycoprotein of 450,000 kDa that has been identified on cell surfaces and in extracellular fluids. It is thought, by virtue of its stickiness, to act as an intercellular cement and maintain microvascular integrity and to act as an opsonin and aid in the phagocytic function of neutrophils and macrophages [112,201]. Generally, the concentration of fibronectin in fetal plasma increases with gestational age to concentrations at term of approximately half the concentrations found in healthy adults [201–203]. Plasma concentrations usually decrease significantly during the course of neonatal sepsis, probably as a result of clearance by the reticuloendothelial system of products of the inflammatory response. The rate of recovery of fibronectin concentrations as infection resolves is relatively rapid, occurring over 5 to 7 days [201,202]. Attempts to characterize a decrease in fibronectin concentrations as a specific marker for sepsis have been disappointing, however [21].

Demonstration of increased amounts of total IgM in umbilical cord sera previously was thought to be helpful in identifying infants with infections acquired in the intrauterine environment, particularly infections caused by rubella virus, cytomegalovirus, *Treponema pallidum*, and *Toxoplasma gondii* [204]. On the basis of this experience, several studies, mainly in the late 1960s and early 1970s, attempted to use serially determined IgM concentrations in the evaluation of infants suspected to have acute postnatal bacterial infections. The sensitivity of IgM concentrations in infants with bacterial sepsis, meningitis, pneumonia, or urinary tract infection is low; specificity was low as well in that viral infections, minor localized bacterial infections, and meconium aspiration were associated with a significant increase in IgM concentrations [21,204–208]. Determination of IgM concentrations as an index of neonatal bacterial infection has largely been abandoned.

The discovery that neutrophils that have phagocytized bacteria reduce nitroblue tetrazolium (NBT) dye to purple formazan led to development of several tests using this leukocyte enzyme activity for detection of bacterial infections involving the systemic circulation [209]. It was shown that in most cases, most peripheral neutrophils reduce nitroblue tetrazolium during the course of an untreated or ineffectively treated infection, whereas only a small proportion of neutrophils do so in the absence of infection. Attempts to incorporate this assay into the newborn period were hampered by difficulty in establishing standard techniques and normal values, and the predictive value of the test was found to be lower than expected [210–215]. The NBT test now is rarely used in the diagnosis of neonatal infection [93]. Many years ago, changes in leukocyte lactate dehydrogenase [216] and in alkaline phosphatase [217] concentrations were thought to be potentially useful indices of neonatal infection. These determinations have received little further attention since that time.

Bacterial infections are known to alter carbohydrate metabolism in neonates. Although hypoglycemia [218] and hyperglycemia [219] have been described in infants with sepsis, the association between changes in blood glucose concentrations and neonatal infection is of limited value as a diagnostic aid.

An exciting discovery in the field of immunology is that multicellular organisms share many evolutionarily conserved aspects of their innate immune systems. Innate immunity depends on molecules such as specialized cellular receptors and binding proteins (e.g., toll-like receptors and mannose-binding proteins), serum complement proteins, and several substances produced and released at the site of infection by neutrophils [220,221]. This last group includes the antimicrobial peptides of the defensin and cathelicidin classes, bactericidal/permeability-increasing protein, lysozyme, and lactoferrin [220–222]. Some of these substances are found in vernix caseosa, the lipid-rich substance covering the skin of the fetus and newborn infant [223]. Further studies on the kinetics of these molecules in health and disease may lead to diagnostic aids for newborn sepsis [222–224].

Finally, sepsis or, more properly, the systemic inflammatory response to sepsis causes hemodynamic changes in regional blood flow. Early in sepsis, peripheral vasoconstriction is seen, whereas in advanced sepsis, generalized vasodilation and shock occur. An interesting concept in diagnostic techniques for neonatal sepsis is to attempt to measure noninvasively deviations in peripheral vascular reactivity or heart rate characteristics. In one small study, newborns with early-onset sepsis (clinical or bacteriologic) had lower degrees of mean peripheral skin perfusion and a higher amount of postocclusion reactive hyperemia as measured by a laser Doppler instrument [175]. The sensitivity and specificity for the measurement of reactive hyperemia were equivalent to or greater than those for measurement of IL-6, IL-8, and TNF-$\alpha$ in this study [175]. A computerized index of reductions in heart rate variability and transient decelerations in heart rate seemed to correlate with late-onset clinical and proven sepsis and, in some cases, predicted sepsis [225].

## MICROSCOPIC EXAMINATION OF PLACENTA, UMBILICAL CORD, GASTRIC ASPIRATES, AND EXTERNAL EAR CANAL FLUID

Microscopic examination of tissues or body fluids is a time-honored but insensitive and nonspecific aid in the diagnosis of neonatal sepsis. An association of neonatal sepsis with pathologic changes in the placenta and umbilical cord was suggested more than 40 years ago [226,227]. Neonatal infection acquired at or about the time of birth often is associated with chorioamnionitis or funisitis [228–230]. Histologic sections of the placenta show acute inflammatory changes, with infiltration of the umbilical vein by neutrophils and gross or microscopic evidence of chorioamnionitis. The probability of finding inflammatory changes in these tissues is inversely related to birth weight and directly related to the duration of rupture of membranes before delivery, the presence of meconium in amniotic fluid, and fetal distress and hypoxia [231–233]. Some inflammatory changes are apparent in the placenta and its membranes or the umbilical cord in 30% of live-born infants [228]. The presence of chorioamnionitis and placentitis does not automatically imply significant neonatal infection.

The stomach of the newborn contains fluid swallowed before and during delivery. The presence of neutrophils and bacteria in a stained smear of the gastric aspirate indicates inflammation of the amniotic fluid, placenta, and other tissues of the birth canal [234,235]. The neutrophils in the gastric aspirate obtained during the 1st day of life are from the mother and do not indicate a fetal inflammatory response [236]. The presence of these maternal leukocytes indicates exposure to possible infection and does not identify an infectious disease in the newborn. After the 1st day, the gastric aspirate contains swallowed bronchial secretions, and examination of a stained preparation may suggest pneumonia in the neonate if inflammatory cells are present [237]. The presence of neutrophils in the aspirated ear canal fluid also indicates exposure to an infected environment. Stained smears and bacterial cultures of neonatal gastric aspirate or external ear canal fluid reflect the flora of the birth canal, and results parallel those of cultures of specimens obtained from the maternal vagina, endocervix, endometrium, and placenta [238–242]. The information obtained does not greatly influence decision making regarding antimicrobial therapy [239].

Pathogens frequently are isolated when daily tracheal aspirates for intubated infants are cultured. Because many (if not all) intubated newborns eventually become colonized with potentially pathogenic microbes, however, the positive predictive value of this test is less than 30% [243]. Similar to gastric aspirates or external ear canal fluid, tracheal aspirates reflect environmental influences, but do not imply sepsis.

Molecular detection tests for bacteria or bacterial products have been applied to amniotic fluid and neonatal blood. The limulus lysate assay for the detection of endotoxin did not prove to be clinically useful [244]. PCR amplification of bacterial DNA from blood seems promising, but is not ready for general clinical use [245,246].

## SCREENING PANELS

The inability of any single laboratory test to provide rapid, reliable, and early identification of neonates with bacterial sepsis has led to efforts to devise a panel of screening tests, combining data from several different determinations, as a means of increasing predictive value.* The results generally have shown little increase in positive predictive value (if a test result is abnormal, disease is present) compared with most individual screening tests, although negative predictive value (if a result is normal, disease is absent) has been remarkably good, approaching 100% in some studies. Performance characteristics of some screening panel tests are summarized in Table 36–3 and compared with single tests.

One attempt to diagnose neonatal sepsis through multiple, simple, standard laboratory determinations involved more than 500 infants younger than 7 days of age studied by Philip and colleagues [20,69,249]. The authors devised a "sepsis screen" for use with infants believed to be at risk for, or showing clinical evidence of, serious bacterial infection. In addition to the standard procedures (blood, CSF, and urine cultures and chest film), the evaluation included a screening panel consisting of total leukocyte count, determination of the I:M ratio, CRP and haptoglobin assays, and microerythrocyte sedimentation rate. An abnormality in any two or more of these items was considered to reflect a "positive sepsis screen," and no abnormality or an abnormality in one item reflected a "negative sepsis screen"; the test turnaround time was 1 hour.

Analysis of the results [20,69] showed a 39% probability that serious bacterial infection was present if two or more test results were positive (positive predictive value) and a 99% probability that infection was not present if only one or no result was positive (negative predictive value). In actual numbers, as a result of the sepsis screen, 60 of 524 infants with clinically suspected sepsis received unnecessary treatment with antimicrobial agents (false positives; specificity of 88%), and 3 with subsequently proven bacterial infection were missed (false negatives; sensitivity of 93%) [69]. Comparable results have been reported by Gerdes and Polin [21], who used a sepsis screen similar to that used by Philip, and by others who used only hematologic or clinical indices [17,45,47,59,95]. Panels of screening tests have not always functioned better than relying solely on the I:T neutrophil ratio, however, particularly in the 1st week of life [20–22,48,59,69,75].

By virtue of its high negative predictive value, the screening panel used by Philip [249] in an intensive care nursery resulted in a significant decrease in the use of antimicrobial agents. Not only did fewer neonates receive antimicrobial agents, but also treatment could be discontinued earlier with greater confidence in the infants who were being administered these agents. Philip [249] was careful to emphasize, however, that screening tests are intended only to augment clinical evaluation. When the evidence obtained by history or physical examination conflicts with a negative screen result, antimicrobial therapy should be started. Similarly, a screening panel combining clinical evaluation and IL-8 and CRP assays led to fewer antibiotic courses being administered compared with neonates treated with standard clinical diagnosis [248]. Neither the IL-8 nor the CRP assays detected all bacteremic neonates at the time of the first evaluation, but when used together as a panel with clinical judgment, greater sensitivity was achieved [248].

An increasingly important area in which a screening test panel might be useful is in the evaluation of asymptomatic infants whose mothers have been given intrapartum antibiotics to decrease the risk of early-onset neonatal group B streptococcal sepsis [6–9]. The American Academy of Pediatrics and the U.S. Centers for Disease Control and Prevention (CDC) recommend that a "limited evaluation," consisting of complete blood cell count and a blood culture, be performed in infants whose mothers met the criteria for intrapartum antibiotic prophylaxis, but who did not receive a complete course of prophylactic treatment [8,9]. The goal is to identify infants with sepsis, including infants whose blood cultures may have been sterilized temporarily by maternal antibiotic prophylaxis.

Ottolini and colleagues [29] tested the utility of a complete blood count screening panel in 1665 infants whose mothers met the criteria for intrapartum antibiotic prophylaxis, but did not receive a full course of treatment. These investigators found that the diagnostic test sensitivity and specificity of an abnormal white blood cell count (i.e., total white blood cell count of $\leq$5000/mm$^3$ or $\geq$30,000/mm$^3$, absolute neutrophil count of <1500/mm$^3$, or I:M ratio of >0.2) were 41% and 73% [29]. Because of the low incidence of true sepsis, even after only partial maternal antibiotic prophylaxis, the positive predictive value of the complete blood count panel was only 1.5%, and the positive likelihood ratio only 1.5. A positive test result was not indicative of newborn sepsis. The negative predictive value of the screen was 99%, implying that a normal test result would at least reassure the clinician that sepsis was not present. The negative predictive value of an infant's appearing asymptomatic also was 99%, however; the complete blood count panel did not add any diagnostic information beyond that gained simply by obtaining a careful history and physical examination of the infant. Similar conclusions were reached by Escobar and associates [85]. The ineffectiveness of the screening panel in these studies may have been due to the low rates of culture-proven sepsis, but many U.S. centers where group B streptococcal sepsis prophylaxis is employed now have such low rates of sepsis.

**Test cutoff refers to the value above which the test result is considered abnormal.*

*CRP, C-reactive protein; IL-6, interleukin-6; I:M ratio, immature-to-mature neutrophil ratio (see text); I:T ratio, immature-to-total neutrophil ratio; PCT, procalcitonin; WBC, white blood cell (total leukocyte) count.*

## PERSPECTIVES AND CONCLUSIONS

As discussed previously, on examining all of the data published to date, it is difficult to choose one cytokine, acute phase reactant, or screening panel for current use as the "best" test (see Table 36–3) [117,183,184,247,248]. Why is this still the case in the 21st century, after so many advances in medical science and biotechnology, and with the plethora of studies of newborn sepsis, or, why has the "ideal test" not been discovered? [10,11] Besides the difficulties in constructing a quick, easy-to-analyze, stable, analytic test with clear diagnostic cutoffs across gestational ages and birth weights and optimal sensitivity and specificity [10,11], there are further clinical epidemiologic constraints in study design that are limiting.

First, some authors do not differentiate between perinatal (early-onset) and postnatal (late-onset) sepsis. This omission can lead to bias because different neonatal pathogens cause early-onset and late-onset disease. Second, because the normal ranges of many analytes vary across gestational and chronologic age, results are again confounded [117,122]. Third, not all reports of neonatal sepsis diagnostic tests include healthy controls, and consequently construction of the normal range of results for an analytic test poses difficulties. Another problem is the lack of universal agreement on the definition of newborn sepsis or systemic inflammatory response syndrome. Some studies restrict the analyses to culture-proven sepsis, although false-negative cultures owing to low blood sample volume or maternal antibiotic therapy may lead to bias. Other studies analyze clinical septicemia, although no universal definition of this entity exists, which also may lead to diagnostic bias; very few studies separately analyze data using proven and clinically diagnosed sepsis [123]. A fifth problem is that the current neonatal illness severity scores (e.g., Score for Neonatal Acute Physiology [SNAP], SNAP-Perinatal Extension [SNAP-PE], Clinical Risk Index for Babies [CRIB]), which theoretically could lead to better stratification of patients and more accurate interstudy comparisons, are cumbersome to use [117,123].

Finally, Chiesa and colleagues [117] noted that "the usefulness of a test will depend, above all, on the clinical condition of the baby. If the baby is really very sick, the test will not give very much additional information . . . if the baby is evidently well . . . a positive test result [will] not dramatically increase the probability that the baby is infected. . .." In other words, it is essential for the clinician to heed bayesian statistical theory—one must consider the pretest (prior) probability (essentially, the disease prevalence) of infection and the test characteristics (sensitivity, specificity) to interpret and apply diagnostic test results properly. Many of these confounding effects can be seen in the data of Table 36–3, in which various studies have used different populations of infants, definitions of sepsis, and laboratory cutoff points, leading to different estimates of the utility of any one laboratory test.

Faced with the imperfection of currently available laboratory aids for the diagnosis of neonatal sepsis, what is today's practitioner to do? History, physical examination, and clinical impression still constitute a large part of clinical medicine, even in the era of molecular diagnostics and therapeutics. A single normal laboratory test should not sway a clinician against empirical therapy for a newborn if it seems to be clinically indicated, and an isolated abnormal test result should not be enough for the clinician to demand therapy. This concept may be restated in diagnostic test statistical terminology as follows: At present, there is no one test or test panel with a high enough positive likelihood ratio or a low enough negative likelihood ratio to recommend it uniquely over all others. The negative predictive values of available tests are not yet high enough, when results are normal, to lead to the withholding of therapy for an uncommon, but possibly life-threatening disease (neonatal sepsis). Conversely, the positive predictive values of available tests are not yet high enough when results are abnormal to lead to routine institution of antimicrobial therapy.

When laboratory testing is combined with clinical impression (and perhaps serial laboratory monitoring), predictive values may increase enough to help the clinician make decisions. When the risk of an uncommon disease with a poor outcome is high, however, and the risk of antimicrobial therapy is low, it may be difficult ever to find a test with predictive values high enough to "rule in" or "rule out" disease with complete confidence.

Clinical judgment, using standardized definitions of historical risk factors, signs, and symptoms, may sometimes perform as well as laboratory screening panels [29,85]. This point may be especially important to remember in resource-poor settings in developing countries [250]. Much future work is needed in the area of rapid diagnosis of neonatal sepsis to move beyond the current best menu of simple, rapid, and inexpensive (albeit imperfect) tests such as total neutrophil counts, total leukocyte counts, I:T ratios, and CRP assay. Continued improvements in blood culture technology are decreasing the time to positivity of neonatal blood cultures, which may at least speed up bacteriologic confirmation of septicemia [251–253].

CHAPTER 37

# Clinical Pharmacology of Anti-Infective Drugs

Kelly C. Wade ✪ Daniel K. Benjamin, Jr.

CHAPTER OUTLINE

## INTRODUCTION

Effective antimicrobial treatment typically begins with empirical therapy at a dose that is most likely to cure the infection with the minimum risk of toxic effects. To select the correct dosage, clinicians need to understand and apply the principles of pharmacokinetics (PK) and pharmacodynamics (PD). This chapter will focus on basic pharmacology and the application of PK and PD principles to the most commonly used anti-infective drugs to guide optimal therapy of common infections in the newborn and young infant.

This chapter proceeds from the exhaustive review of the pharmacology of antimicrobial agents provided by Drs. Sáez-Llorens and McCracken in the previous edition. In areas in which information remains relevant and unchanged, I acknowledge their efforts and permission to use a previous text. Since the previous edition of this book was published, more relevant PK data have been reported. Additional studies have supported an integrated PK and PD (PK-PD) approach to antibiotic therapy. Finally, the range of antimicrobial drugs discussed has been expanded to include antifungal and non-HIV antiviral medications. Information on antimicrobial drugs that are no longer used or rarely used has been omitted to make room for new information.

The clinical pharmacology, indication, dosing, and toxicity of licensed drugs are included in the label and available through the Physicians' Desk Reference (www.pdr.net) [1] and the Federal Drug Administration (FDA) Center for Drug Evaluation and Research (www.fda.gov/cder/) [1]. However, the use of many drugs remains off-label in term and premature neonates due to inadequate PK and efficacy studies. In this chapter drugs are organised into the following five categories of efficacy: (1) gram-positive infections including MRSA, (2) gram-negative infections, (3) polymicrobial or complicated serious infections, (4) viral infections, and (5) fungal infections. The pharmacology of drugs in neonates is unique and should not be extrapolated from data derived from studies in older patients whenever possible. Few drugs have been adequately studied in the extremely preterm infant so many of the dosing guidelines in this high-risk patient group remain empirical. In such cases, we will review the mechanism of action and dosing relative to known PK-PD properties and safety.

DOI: 10.1016/B978-1-4160-6400-8.00037-7

**TABLE 37–1** Drugs Not Routinely Used in Neonates

| Drug | Potential Adverse Effect | References |
|---|---|---|
| Tetracycline | Depressed bone growth and teeth abnormalities | [90,117,662] |
| Chloramphenicol | Circulatory collapse, impaired mitochondrial protein synthesis, bone marrow aplasia; gray baby syndrome | [2,3,5,6,663] |
| Sulfonamide | Bilirubin displacement with rare but possible kernicterus; increased risk of hemolysis in G6PD-deficient infants | [21,664] |
| Trimethoprim-sulfamethoxazole (available in 1:5 ratio) | Same as sulfonamide; bilirubin displacement with rare but possible kernicterus; increased risk of hemolysis in G6PD-deficient infants | [1,665] |
| Ceftriaxone | Highly protein bound, potential to displace bilirubin; cannot be coadministered with calcium containing fluids | [1,20] |

A few antimicrobial drugs have been associated with serious toxicity (Table 37–1) and therefore their use in neonates is discouraged in developed countries. The most notable on this list is chloramphenicol. Chloramphenicol has been associated with circulatory collapse, otherwise known as gray baby syndrome, and death in infants due to drug accumulation following excessive dosages. This complication can be traced to immaturity of the glucuronyl transferase activity in the fetus and young newborn infants, coupled with diminished renal function [2–6]. Chloramphenicol toxicity appears to be related to impaired mitochondrial protein synthesis and to direct inhibition of myocardial contractile activity. Since this toxicity results from free drug accumulation, multiple exchange transfusions or charcoal hemoperfusion may reverse the clinical syndrome by removing the free drug from the blood [7–9]. Anemia due to dose related marrow suppression is the most common untoward reaction to chloramphenicol; however, severe idiosyncratic bone marrow aplasia occurs in approximately 1 in 40,000 patients of all ages receiving the antibiotic [3].

## BASIC PRINCIPLES OF CLINICAL PHARMACOLOGY

The rapidly changing physiologic processes characteristic of fetal and neonatal development profoundly affect the PK properties of antibiotics [10–12]. Maturation affects total body water, drug metabolism, and drug elimination. Gastric absorption is highly variable. These changes can result either in subtherapeutic drug concentrations, thereby delaying bacterial eradication, or in toxic drug concentrations that cause morbidity. Common PK terms and abbreviations are defined in Table 37–2.

The PK of a drug describes the relationship between drug dose and subsequent concentration in the blood over time. Four basic components explain the PK of a drug: absorption, distribution, metabolism, and excretion. Absorption of drugs administered at extravascular sites typically occurs by passive diffusion across biologic membranes. This process is affected by chemical properties of the drug, such as its molecular weight, ionization, and lipid solubility, and by physiologic factors, such as local pH and blood flow, which undergo developmental changes as the newborn matures. The severity of infections and the inconsistent absorption after extravascular administration warrant most antimicrobial therapy to be delivered by the intravenous route in developed countries.

**TABLE 37–2** Common Pharmacokinetic Terms

| PK Term | Abbreviation | Definition | Units |
|---|---|---|---|
| Maximum concentration | $C_{max}$ | Maximal drug concentration at end of infusion. Alternatively, for drugs that are rapidly distributed (α-phase), the peak concentrations may be evaluated 30 minutes after end of infusion to give the concentration after the initial rapid phase of distribution | μg/mL or mg/L |
| Minimum concentration | $C_{min}$ | Minimal drug concentration just before subsequent dose | μg/mL or mg/L |
| Clearance | Cl | The amount of blood from which all drug is removed per unit of time through both renal and nonrenal mechanisms | (mL/min)/kg<br>(L/hr)/kg |
| Volume of distribution | Vd | Hypothetical volume of fluid through which a drug is dispersed | L/kg |
| Elimination rate constant | $k_e$<br>$k_e$ = Cl/Vd | For drugs with first order kinetics, the ratio of clearance to volume of distribution (Cl/Vd) | 1/hr or $hr^{-1}$ |
| Half-life | $t_{1/2}$ of β-phase = (0.693)/ke | Time it takes to clear half of the drug from plasma. It is directly proportional to the Vd and inversely proportional to Cl. | hr |
| Bioavailability | F | The fraction of the administered dose that reaches the systemic circulation. F = 1 for intravenous administration. After oral administration, F is reduced by incomplete absorption, first-pass metabolism, and distribution into other tissue. | % |
| Area under the concentration time curve | AUC | Measure of total drug exposure, typically over 24-hour period | mg * L/hr |

Oral absorption of antimicrobial agents is difficult to predict and can only be determined by carefully executed experiments. Bioavailability describes the fraction of an administered dose of a drug that reaches the systemic circulation. By definition, intravenous medications have 100% bioavailability. However, oral medications have decreased bioavailability due to incomplete absorption and first-pass hepatic metabolism. Unique neonatal features that impact absorption changes with gestational and chronologic age include the alkaline gastric pH, slow gastric emptying, high gastrointestinal-to-whole body surface area ratio, increased permeability of bowel mucosa, irregular peristalsis, prolonged intestinal transit time, differences in first pass hepatic metabolism, and the deconjugational activity of the intestinal enzyme β-glucuronidase [10].

Intramuscular absorption of antimicrobial agents is generally comparable to intravenous administration; however, substantial differences can exist because intramuscular antibiotic absorption is dependent upon regional blood flow [13,14]. Intramuscular absorption can be profoundly reduced in infants with hypoxia, hypotension, or poor tissue perfusion.

After drug absorption into the bloodstream, the dose of a drug is distributed into all of the body compartments and tissues that the product is physically able to penetrate, including water compartments and adipose tissue. This distributive phase is typically rapid, and the drug is said to distribute into its volume of distribution or Vd. This volume is considered hypothetical because it is based on sampling drug concentrations in serum or plasma after dosing. Interpretation of these samples requires the assumption that the drug is uniformly distributed throughout the body. However, drugs do not distribute in a uniform fashion. Drugs that are water soluble or highly bound to plasma proteins have a high plasma concentration and a low volume of distribution because the drug tends to remain in the blood. Drugs that are lipid soluble or bind extensively to tissue are present in the plasma in low concentrations and therefore have large volumes of distribution. Volume of distribution in the neonate is usually larger than in children (and premature infants larger than in term infants) due to the larger extracellular water compartment in neonates.

The extracellular fluid volume in newborns is considerably greater than that in children and adults. In the first 3 months of life, it decreases from 7.3 to 5.8 $L/m^2$ and then remains nearly constant throughout infancy and early childhood [15]. Extracellular fluid volume is also increased with prematurity, so that peak serum concentrations are lower in preterm infants compared with term infants after similar dosages. Expanded extracellular volumes prolong drug elimination and lead to longer half-lives. The clinical application of these concepts is particularly relevant to aminoglycosides because the efficacy is associated with the peak concentration whereas toxicity is associated with trough concentrations.

Protein binding can also impact drug distribution and elimination. Quantitative and qualitative differences exist between the serum proteins of newborns and those of older infants [16]. These differences affect the degree to which antimicrobial agents are protein bound. Variables that impact protein binding include concentrations of plasma proteins (such as albumin), concentration of drug, drug affinity for protein-binding sites, presence of competing substances for protein-binding sites (e.g., furosemide, bilirubin), and plasma pH. Protein-bound drug has negligible antibacterial activity and remains in the intravascular space with limited distribution into tissue and limited excretion. Because only free drug is active and available for elimination, changes in protein binding can dramatically affect exposure and efficacy. Protein binding for some antibiotics is lower in neonates than in adults so extrapolation is not advised [17] and the PK of the free drug needs to be determined.

Some antibacterial agents are capable of displacing bilirubin from albumin-binding sites, including the sulfonamides, moxalactam, cefoperazone, and ceftriaxone [18–20]. Theoretically, jaundiced neonates receiving these antibiotics are at increased risk of developing kernicterus. This complication, however, has been documented only for sulfonamides [21]. Most antimicrobial drugs do not displace bilirubin because most have a much lower binding affinity for albumin than bilirubin [22], and thus the extent of protein binding by an antibiotic does not necessarily correlate with bilirubin displacement [19,23–25].

Drugs start to be eliminated from the body as soon as they are delivered. If doses are given at a rate that balances the drug clearance rate, then target steady state drug concentrations can be maintained. Drug clearance is the volume of blood, serum, or plasma completely cleared of drug per unit of time and is expressed units of volume/time, for example L/hour or mL/min. Clearance is not only related to infant size (L/hour/kg), but also to clinical characteristics such as renal disease, hepatic disease, and drug interactions. Clearance of water soluble drugs usually occurs via excretion into the urine; while lipid soluble drugs are often metabolized to water-soluble metabolites by the liver before they can be excreted.

Drug elimination occurs through hepatic metabolism, renal excretion, or both, and is affected by physiologic maturation [10,12]. Hepatic metabolism involves chemical transformation of the drug into a form that is more fat-soluble for elimination in the bile and feces, or a form more water-soluble for elimination by the kidneys. The ontogeny of the cytochrome P450 metabolizing enzymes in newborn development has been evaluated and reviewed [12,26]. Newborns are at risk for toxicity from drug accumulation due to deficiencies in hepatic glucuronyl transferase or hepatic esterases. Drugs can also induce enzyme production leading to drug interaction. Phenobarbital stimulates hepatic enzyme production, thereby increasing the clearance and lowering serum concentrations of some drugs including anticoagulants, corticosteroids, phenytoin, metronidazole, and theophylline.

Renal elimination of active drug or metabolites occurs via glomerular filtration and/or tubular secretion. Some drugs are reabsorbed in renal tubules, thus further altering their elimination rate. Renal function varies with gestational age, chronologic age, and disease state. The constant state of renal function fluctuation has a profound impact on antibiotic PK. In newborns, the glomerular filtration rate is 30% to 60% of adult levels. A remarkable increase in renal function occurs over the first 2 weeks

of life [12,27]. As a result, sustained serum concentrations and prolonged half-life values of many drugs eliminated through the kidneys are observed in the first days of life. After birth, renal function improves more slowly in premature infants, leading to prolonged drug elimination over the first few weeks of life. Drug elimination is also reduced in sick infants due to decreased renal blood flow resulting from respiratory insufficiency, hypotension, or dehydration. For example, hypoxemic infants have a prolonged serum half-life of aminoglycosides [28]. Because renal function is constantly changing in the first month of life, a PK profile is determined on multiple occasions during this period to define the proper dosage and frequency of administration of an antibiotic.

Most drugs are cleared through first order elimination. This means that a constant proportion of drug is cleared per unit of time. Initially, there is a steep fall in concentration, after which the decline becomes shallower as the amount of drug remaining decreases. When the concentration time profile is plotted on a log-linear scale, the decline is linear because the shape of the relationship between concentration and time is described by an exponential function. The elimination rate constant ($k_e$) is the ratio of clearance to volume of distribution and is usually expressed in units of L/hour.

Each patient has a unique elimination rate constant that reflects the clearance and volume of distribution of the drug. The elimination rate constant can be converted into the clinically meaningful concept of drug half-life, the time it takes for the concentration of a drug to fall to half. The half-life of a drug is estimated by the equation $t_{1/2} = 0.693/k_e$ because the exponential log of 0.5 is 0.693. Half-life estimates are patient specific. For drugs eliminated by first order kinetics, the elimination rate constant represents the ratio of drug clearance and volume of distribution. For patients with renal insufficiency, delayed renal clearance of gentamicin will result in a half-life that can be three times as long as patients with normal renal function. Patients with fluid overload have a large volume of distribution and a longer half-life, and therefore may need to receive a higher dose of medication less frequently.

## OPTIMIZING ANTIMICROBIAL THERAPY USING PK-PD PRINCIPLES

Optimizing antimicrobial therapy in neonates requires a thorough understanding of the relationship between dose and exposure (PK) and between exposure and optimal response to therapy (PD) [29,30]. Our goal is an integrative approach using knowledge from microbiology (MIC, MBC), PK, and PD such that we can have a high probability that a specific dose of an antibiotic can cure a particular infection in a defined population of infants. Carefully designed clinical trials can then be performed to confirm the results of such an integrative modeling and simulation approach.

### Minimal Inhibitory Concentration

The in vitro drug susceptibilities of commonly encountered bacterial pathogens allow comparison of potencies for eradication. Ideally both the minimal inhibitory concentration (MIC) and the minimal bactericidal concentration (MBC) should be determined. To account for the great variation in pathogens and susceptibilities in different nurseries and geographic regions, this knowledge can be generated for each specific newborn unit. The higher the MIC, the more difficult it is to eradicate a pathogen with that drug, even if the MIC falls within the established sensitive range.

### *Pharmacokinetic Data*

New analytical techniques and the computer algorithms for population PK model analysis have made PK evaluation of drugs in infants more feasible. PK explains the relationship between drug dose and the concentration of drug in the plasma or serum over time. PK studies are performed after a single dose and after multiple doses to determine concentrations at steady state. Drug levels can now be measured using mass spectroscopy in as little as 0.1 mL volume obtained by heel stick. For drugs that exhibit protein binding, it is important to measure the quantity of total and nonprotein bound drug. Subsequently, multiple serum samples are obtained to determine concentrations of the drug at a given time after the dose. The serum half-life and volume of distribution are calculated by plotting the serum concentration-time curves and calculating the clearance, a measure of the disappearance of drug from serum [31]. Population PK analysis allows investigators to study a medication in a diverse group of preterm and term infants of different ages so that changes in drug clearance and volume of distribution can be explained by maturational covariates (gestational age at birth, chronologic age, weight, or renal function) in a mathematical model. Monte Carlo simulation using these models of drug clearance and volume of distribution is used to predict and compare drug exposure from different dosing regimens to provide dose adjustments for maturational changes in an infant.

It is clinically important to determine the active drug concentrations in the cerebrospinal fluid (CSF) [32]. CNS penetration of drugs is usually expressed as the fraction of cerebrospinal fluid (CSF) drug concentrations divided by the plasma or serum concentrations since most studies link a single CSF sample with a simultaneous blood sample. In the 1980s, new antibiotics were tested in a rabbit model of meningitis before use in infants to determine the CSF penetration and bactericidal activity of the drug against commonly encountered meningeal pathogens [33–35]. More data are needed to understand the CSF penetration of antimicrobial drugs in the presence or absence of meningitis in neonates. Some current antimicrobial trials attempt to collect CSF from standard of care sampling to measure drug levels in CSF.

### *Pharmacodynamics*

PD equations describe the relationships between the drug concentration-time profile and the ability to eradicate the organism, prevent emerging resistance, and minimize adverse effects. Dose and time of infusion determine the maximum drug concentration achieved. Dose and dosing interval determine the overall drug exposure per 24-hour

interval (24-hour area under the concentration curve [AUC]) and the minimum concentration between dosing intervals. Bacterial eradication is typically evaluated in relation to the maximum drug concentration, the AUC, and the percent of time that the drug concentration is above a minimum threshold, as determined by the MIC of the target organism.

### *Pharmacokinetic/Pharmacodynamic Approach*

To achieve the best therapeutic response, drug dose should be related to antimicrobial effect through an integrated PK-PD approach, in which a dose is chosen to target a therapeutic drug concentration relative to the MIC of the offending organism [30]. Three important PK parameters are the peak serum level ($C_{max}$), the trough level ($C_{min}$), and the AUC (Tables 37–2, 37–3). These PK-PD parameters are used to quantify the activity of an antibiotic. Antimicrobial agents are typically associated with one of three patterns of activity (Table 37–3, Figure 37–1) [29,30,36,37]: (1) those that exhibit concentration-dependent killing and prolonged persistent postantibiotic effects, and thus achieve optimal killing when the maximal concentration exceeds a threshold Peak/MIC ratio. These products have additional impact related to the total drug exposure AUC/MIC ratio; (2) agents that exhibit time-dependent killing patterns and therefore achieve optimal killing when the duration of drug exposure above a MIC exceeds a percent of time greater than MIC; (3) agents that are most effective when the maximal total drug exposure exceeds a threshold AUC/MIC ratio. Threshold PK-PD therapeutic exposure targets are determined through in vitro experiments, animal models, and human studies that relate drug exposure to MIC and efficacy.

**TABLE 37–3** PK-PD Relationships for Optimal Antimicrobial Treatment

| Antimicrobial Activity | PK-PD Parameter and Goal of Therapy | Definition | Drug Class | Dosing Goal |
|---|---|---|---|---|
| Concentration-dependent killing with postantibiotic effect | $C_{max}$/MIC | Bacterial killing is proportional to maximal concentration achieved relative to MIC of offending organism | Aminoglycosides<br>Fluoroquinolones<br>Daptomycin | Enhance peak concentration |
| Time-dependent killing | T>MIC | Bacterial killing is proportional to the amount of time the drug concentration is maintained above the MIC of offending organism | β-lactams:<br>Penicillins<br>Cephalosporins<br>Carbepenems | Enhance duration of exposure by short dosing intervals |
| Time-dependent killing with postantibiotic effect | AUC/MIC | Bacterial killing is proportional to the amount of total drug exposure relative to MIC of offending organism | Vancomycin<br>Clindamycin<br>Linezolid<br>Azoles | Enhance amount of drug using both dose and interval |

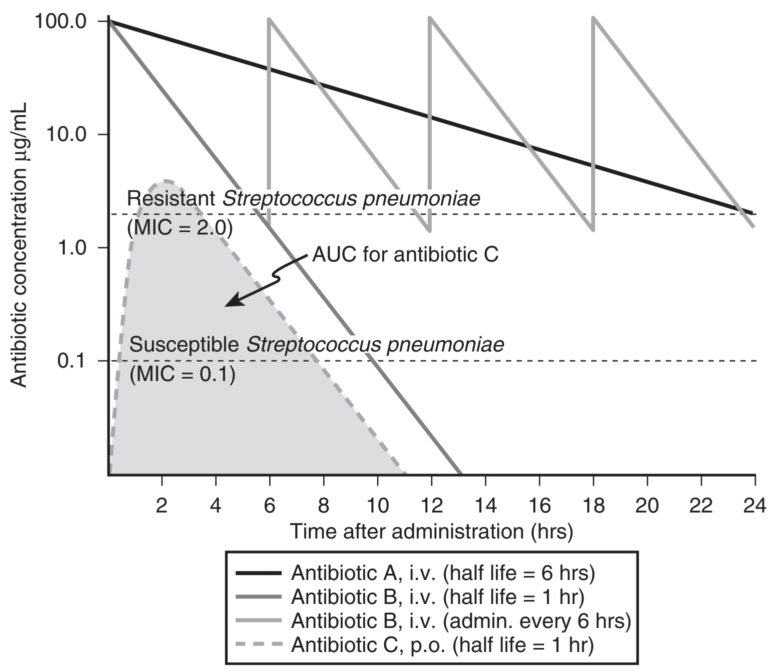

**FIGURE 37–1 Effects of dose (mg/kg), dosing interval, and route of administration on total drug exposure as defined by the AUC and its relationship to the MIC of the pathogen being treated.** Antibiotics administered intravenously with a long serum half-life of 6 hours (antibiotic A) achieve a relatively large AUC compared with antibiotics with a shorter half-life of 1 hour (antibiotic B), which require more frequent dosing (every 6 hours in this example) to achieve similar drug exposure to the pathogen. Orally administered antibiotics (antibiotic C) generally produce a much lower AUC than those administered intravenously. The MICs for penicillin-susceptible and penicillin-resistant *S. pneumoniae* are superimposed on the graph. *(From Bradley JS, Dudley MN, Drusano GL. Predicting efficacy of antiinfectives with pharmacodynamics and Monte Carlo simulation. Pediatr Infect Dis J 22:982–992, 2003, quiz 993–995.) [36]*

## PLACENTAL TRANSPORT OF ANTIBIOTICS

Antimicrobial agents are prescribed for approximately 20% of pregnant women [38,39], and many of these drugs are given at the end of pregnancy for amnionitis or intrauterine bacterial infections. Understanding placental transport is therefore an important component of antimicrobial therapy in the neonate.

Drugs may be transported across the placenta either passively, by simple diffusion, or actively, by energy-dependent processes [40]. Factors influencing transplacental passage include lipid solubility, degree of ionization, molecular weight, protein-binding affinity, surface area of the fetal-maternal interface, placental blood flow, stage of pregnancy, and placental metabolism. Placental drug biotransformation ensues by oxidation, reduction, hydrolysis, or conjugation with endogenous chemicals. In addition, antibiotics concentrate to various degrees in fetal tissues, depending on lipid solubility, specific binding to biologic constituents, changes in fetal circulation, and gestational age.

Ratios of infant to maternal serum concentrations of commonly-used antimicrobial agents are shown in Table 37–4 [2,41–84]. Maternal serum concentrations are usually lower than those reported in nonpregnant women because of a larger plasma volume and an increased renal plasma clearance during pregnancy [85,86]. Due to differences in maternal dosage, route of administration, gestational age, timing of sample collection, and methods of measuring antimicrobial activity, a wide range of serum values for pregnant women and infants and of percentages of transplacental penetration is obtained for most drugs.

**TABLE 37–4** Transplacental Passage of Antimicrobial Agents

| Antimicrobial Agent | Trimester | Serum Infant-to-Maternal Ratio(s) (%) | Potential Adverse Effects on Fetus or Infant | Reference |
|---|---|---|---|---|
| Amikacin | 1, 2 | 8–16 | Ototoxicity | [43] |
| | 3 | 30–50 | | [44] |
| Amoxicillin | 3 | 30 | None | [45] |
| Ampicillin | 1, 2 | 50–250 | None | [46] |
| | 3 | 20–200 | | |
| Cefazolin | 1, 2 | 2–27 | None | [48–50] |
| | 3 | 36–69 | | |
| Cefoperazone | 3 | 33–48 | None | [51,52] |
| Cefotaxime | 2 | 80–150 | None | [53] |
| Ceftriaxone | 3 | 9–120 | None | [54] |
| Cefuroxime | 3 | 18–108 | None | [55,56] |
| Cephalexin | 3 | 33 | None | [58] |
| Chloramphenicol | 3 | 30–106 | Circulatory collapse | [2,60,61] |
| Clindamycin | 2 | 10–25 | None | [41,48] |
| | 3 | 30–50 | | [62] |
| Cloxacillin | 3 | 20–97 | None | [48,63] |
| Dicloxacillin | 3 | 7–12 | None | [48,64,66] |
| Erythromycin | 2, 3 | 1–20 | None | [41,67] |
| Gentamicin | 2, 3 | 21–44 | Ototoxicity; potentiation of $MgSO_4$-induced neuromuscular weakness | [68,69] |
| Imipenem | 3 | 14–52 | Seizure activity | [70] |
| Kanamycin | 3 | 26–48 | Ototoxicity | [48,71] |
| Nafcillin | 3 | 16 | None | [48] |
| Nitrofurantoin | 3 | 38–92 | Hemolysis in G6PD deficiency | [73] |
| Penicillin G | 1, 2 | 26–70 | None | [46,48] |
| | 3 | 15–100 | | [46,48,74] |
| Sulfonamides | 3 | 13–275 | Hemolysis in G6PD deficiency; jaundice and potential kernicterus | [75–80] |
| Tetracyclines | 3 | 10–90 | Depressed bone growth; abnormal teeth; possible inguinal hernia | [48,50,81–83, 90,91,662,666] |
| Tobramycin | 1, 2 | 20 | Ototoxicity | [42,48] |
| Trimethoprim | 1, 2 | 27–131 | Teratogenic in animals | [83,84,665] |

From Table 37–4 it can be seen that infant serum concentrations of some antibiotics, such as ampicillin [46], cefotaxime [53], chloramphenicol [60,61], and sulfonamides [75,76,80,87], approach or even exceed those in maternal serum. These high and rapidly attainable fetal ampicillin serum concentrations explain, in part, the benefit of intrapartum administration of ampicillin to pregnant women colonized with group B streptococci in reducing early-onset neonatal sepsis. The ratio of infant to maternal serum values for methicillin [66,72] is considerably higher than that for dicloxacillin [64,66]; this may be a result of differences in serum protein binding (37% and 98%, respectively). Antibiotics with low transplacental penetration include cephalothin [59,65], dicloxacillin [64,66], erythromycin [41,67], nafcillin [48], and tobramycin [42,48].

Complete evaluation of the possible adverse effects of drugs on the developing fetus must be performed before the drug is used during pregnancy. Some reported adverse events associated with antibiotics [88,89] include kernicterus (sulfonamides), ototoxicity (streptomycin), inhibition of infant bone growth (tetracyclines), and discoloration of teeth (tetracyclines). Anecdotal clinical experience is not sufficient to assess properly the safety of antibiotic administration during pregnancy. Rather, carefully planned prospective toxicity studies in the fetus and neonate, first in animals and then in humans, are warranted.

Due to the ease of transplacental passage of sulfonamides and their significant bilirubin-displacing capabilities, with the associated theoretical risk for development of kernicterus in the infant, these drugs should not be given to pregnant women near term [78]. Jaundice and hemolytic anemia have been noted in newborns with G6PD deficiency after maternal sulfonamide administration near term.

The tetracyclines readily cross the placental barrier and concentrate in many tissues of the developing fetus [83]. Of particular interest is the deposition of tetracycline in fetal bones and deciduous teeth [81–83,90,91]. Calcification of deciduous teeth begins during the fourth month of gestation, and crown formation of the anterior teeth is almost complete at term. Tetracycline administered during this gestational period produces yellow discoloration, enamel hypoplasia, and abnormal development of those teeth. These effects have been documented for tetracycline, oxytetracycline, and demethylchlortetracycline. One report found a possible association between ciprofloxacin therapy given to young infants and teeth discoloration [92], but this association has not been confirmed in other studies.

Chloramphenicol has been associated with circulatory collapse (gray baby syndrome) and death in premature infants who received the drug during the first weeks of life [2]. Chloramphenicol should not be administered to pregnant women near term because of the absence of glucuronyl transferase activity in the fetal liver and the potential danger of serum drug accumulation and shock in the newborn [93].

## EXCRETION OF ANTIBIOTICS IN HUMAN MILK

Approximately 20% of postpartum women are prescribed an antibiotic; [94] however, the concentration of antimicrobial agents in breast milk is typically so low that neither therapeutic nor harmful effects are likely to occur. The amount of drug could be significant if the drug accumulates in breast milk, the infant ingests a large volume of milk, infant feeding times correlate with maximal maternal plasma concentrations, or the drug has reasonable bioavailability in the infant [95,96]. Assessment of the safety of antibiotics in milk has relied primarily on anecdotal clinical experience, rather than on carefully controlled long-term studies.

Most drugs are transferred into breast milk by passive diffusion, exocytosis, or reverse pinocytosis [95]. Factors influencing the transfer of antibiotics from plasma to milk include maternal serum concentration of unbound drug and the physiochemical properties of the drug (e.g., molecular weight, lipid solubility, degree of ionization, and protein-binding capability) [95–98]. Small, lipid-soluble, nonionized drugs traverse the lipid bilayers into breast milk more readily than larger, ionized, water soluble drugs. Although drugs with high lipid solubility tend to accumulate in milk, the extent varies with the fat content of the milk. The ionization power of drugs depends on the pH of the milk and the drug dissociation constant (pKa). Weak bases become more ionized with decreasing pH. Early postpartum human milk has a pH of 7.0 to 7.1, while mature milk after 2 weeks has a pH of approximately 7.3 to 7.4, each compared with the normal serum pH of 7.35 to 7.45. Therefore, drugs that are weak bases (pKa greater than pH), such as erythromycin, isoniazid, metronidazole, and tetracyclines, would be expected to ionize and accumulate in the lower pH environment of colostrum. Weak acids, such as ampicillin, are more likely to be ionized in maternal serum and therefore not transfer at high levels into breast milk. Drugs that are highly serum protein-bound, such as ceftriaxone, tend to remain in the intravascular space in the maternal circulation. Data pertaining to antibiotic concentrations in the colostrum are not available. Because blood flow and permeability are increased during the colostral phase [97], it is possible that these drugs are present in concentrations equal to or greater than those found in mature milk.

The maternal serum and breast milk concentrations of commonly used antimicrobial agents have been reviewed [52,95,99,100]. Milk to plasma ratios show considerable variability due to the extremely small number of women studied and the differences in age, gestation, dosing regimen, and underlying pathophysiology. In general, the concentrations of metronidazole, sulfonamides, and trimethoprim in breast milk are similar to those in maternal serum (milk-to-serum ratio of 1.0), whereas those of chloramphenicol, erythromycin, and tetracycline are 50% to 75% of maternal serum values. The concentrations of penicillins, oxacillin, various cephalosporins, and aminoglycosides in milk are low.

Although the milk-to-plasma ratio is frequently quoted to predict drug distribution into breast milk, its utility for those drugs with higher milk-to-serum ratios is suspect. The milk-to-plasma ratio is typically obtained at a single point in time. However, the concentration of drug in breast milk and plasma is not constant and the ratio of milk-to-plasma concentrations varies greatly over time. Most studies are not performed at steady state. Furthermore, most studies usually do not expose the infant to the breast milk and

cannot comment on infant systemic exposure. Instead, Chung et al recommend that the milk-to-plasma ratio be used as a qualitative estimate of the possible magnitude of infant drug exposure [95]. By taking the peak breast milk concentration and an assumed ingestion of breast milk intake (150 mL/kg/day), they have derived an estimated potential infant dose correlated with predicted infant exposure (Table 37–5 modified with permission from Chung and coworkers) [95]. In addition, infant maturity, developmental characteristics of drug disposition, and tolerance of drug when given directly to the infant, and the possible extent to which the drug may modify the infant's intestinal gut flora need to be taken into consideration.

Most drugs are predicted to yield breast milk concentrations that produce limited exposure to newborns (Table 37–5). Single dose PK studies describe very limited breast milk concentrations after maternal administration of penicillin, amoxicillin, ticarcillin, cephalosporins [54, 101–108]. For mother's receiving ampicillin, additional studies confirmed minimal concentration of ampicillin in breast milk concentration and minimal to no infant exposure [105,109,110]. Clavulanic acid was not detected in breast milk [105]. One study observed higher than expected concentrations of ceftazidime in breast milk from women receiving a high dose regimen at steady state [111]. The predicted infant ceftazidime exposure remains limited especially given the poor bioavailability of ceftazidime. The overall tolerability profile of penicillin and cephalosporins, along with the low concentration of these drugs in breast milk, support their use in breast-feeding infants [112].

**TABLE 37–5** Summary of Reported Breast Milk Concentrations of Selected Antibiotic and Estimated Maximal Potential Infant Daily Dose for Medications That Distribute into Breast Milk*

| Drug (No. mothers studied) | Maternal Dose Regimen† | Peak Milk [mg/L]‡ | Corresponding Potential Infant Dose§(mg/kg/day) | Infant Clinical Dose (mg/kg/day) | Theoretical Safety Concerns | Reference |
|---|---|---|---|---|---|---|
| **Drugs for which the effect on nursing infants is unknown but may be of concern, consider discarding breast milk in most circumstances** | | | | | | |
| Metronidazole | 2 g once | 45.8 | 6.87 | 7.5–30 | In vitro mutagen | [120,667,668] |
| Metronidazole | 400 mg tid for 3–4 days | 15.5 | 2.44 | 7.5–30 | | |
| Chloramphenicol | 250 mg q6h for 7–10 days | 2.8 | 0.43 | 50–75 | Idiosyncratic bone marrow suppression. | [669–671] |
| Chloramphenicol | 500 mg q6h for 7–10 days | 6.1 | 0.92 | 50–75 | Extremely unlikely to achieve levels to cause gray baby syndrome | [5,6] |
| **Maternal medication usually compatible with breast-feeding with ongoing observation of infant** | | | | | | |
| Erythromycin | 2 g/day | 3.2 | 0.48 | 15–50 | GI distress, pyloric stenosis | [52,118] |
| Azithromycin | 1g then 48 hr later 500 mg/day for 3 days | 2.8 | 0.42 | 5–10 | GI distress | [672] |
| Clindamycin | 600 mg q6h | 3.8 | 0.57 | 25–40 | *C. difficile* colitis | [119,673] |

The rare possibility of hypersensitivity reactions or altered intestinal flora–associated diarrhea in breast feeding infants remains a theoretical concern.

Broad-acting agents should be reserved for the most serious infections. The most recent review of antibiotics in breast-feeding [95] reported personal communication with Merck of limited data on detectable low levels of imipenem in breast milk of women, typically 0.2 to 0.5 mg/L. Cilastin was not detected. Despite this low exposure in breast milk, infant exposure would be further limited by poor bioavailability and drug inactivation at alkaline or acidic pH. The similarities in drug characteristics of meropenem and imipenem suggest that breast milk exposure from meropenem would be minimal. The physiochemical properties of aztreonam suggest limited transfer into breast milk since it is inactivated in acidic solutions and exhibits moderate protein binding and low lipid solubility [1]. Single dose PK studies confirmed a minimal amount of aztreonam in breast milk of women [113].

The physiochemical properties of fluoroquinolones (weak acid, low molecular weight, high lipid solubility, low protein binding, and good bioavailability) suggest that fluoroquinolones can accumulate in breast milk; [1,114] however, the predicted infant dose exposure is limited (see Table 37–5) and a case report of one infant revealed negligible ciprofloxacin infant serum concentrations (<0.03 mg/L) despite accumulation in breast milk after 10 days of maternal exposure (maternal serum 0.21 mg/mL, breast milk 0.98 mg/L) [115]. This report highlighted the difficulty of predicting infant exposure from maternal plasma and milk concentrations. The risk of fluoroquinolone-induced arthropathies or cartilage erosion in neonates has not been explored. Although the predicted fluoroquinolone exposure to an infant is predicted to be negligible, most recommend against the use of a fluoroquinolone while breast-feeding due to theoretical concerns for adverse events.

Sulfonamides and tetracycline both distribute relatively poorly into breast milk yet have theoretical concerns for associated adverse events in neonates [52]. The amount of sulfamethoxazole and tetracyclines in breast milk is low and of unclear clinical significance. One breast-fed infant with G6PD deficiency experienced hemolytic anemia while the mother was receiving sulfamethoxypyridazine [116]. The adverse effects of tetracyclines on developing teeth and bones are well documented when the drug is given directly to infants and children; however, the limited exposure in breast milk has not been directly associated with abnormalities [82,90,117]. Although many use these theoretical concerns to discourage breast-feeding during maternal exposure to sulfonamides or tetracyclines, the American Academy of Pediatrics states that sulfapyridine, sulfafurazole, and sulfamethoxazole (with trimethoprim), tetracycline, doxycycline, and minocycline are compatible with breast-feeding. Caution is advised for infants with jaundice, G6PD deficiency, severe illness, or significant prematurity [112].

Macrolides, azithromycin, and clindamycin distribute into breast milk. However, the actual amount the infant would receive from breast-feeding remains very small (see Table 37–5). Neonatal exposure may be further limited by bioavailability. One case report of erythromycin-induced pyloric stenosis during breast-feeding exposure in a 3-week-old infant has been reported [118]. One report incriminated the administration of clindamycin to a mother in the development of antibiotic-induced colitis in her breast-fed infant [119]. The American Academy of Pediatrics has described erythromycin and clindamycin as usually compatible with breast-feeding [112]. Azithromycin is likely to be compatible with breast-feeding as well [95].

Metronidazole effectively distributes into breast milk and achieves infant plasma concentrations approximately one-fifth the exposure observed in the mother's plasma [120]. Breast-fed infants whose mothers were administered metronidazole therapy had no difference in adverse events compared with infants whose mothers received ampicillin or no antibiotics. Metronidazole has been detected in infant plasma and has potential carcinogenesis or mutagenesis properties in vitro and in mice [121–123]. Although the extrapolation of mutagenesis properties in humans remain unknown [124,125], clinicians often consider withholding breast-feeding during maternal metronidazole exposure [112].

The decision to allow or stop breast-feeding is based on the likelihood that high milk concentrations are attained for a particular antibiotic, whether the drug is expected to be absorbed into neonatal plasma, and whether significant adverse events are commonly associated with this agent. The American Academy of Pediatrics Committee on Drugs recommends that breast-feeding be transiently discontinued during the course of treatment with metronidazole (an in vitro mutagen) or chloramphenicol (associated with a theoretical risk of idiosyncratic bone marrow suppression), and cautions with the use of nalidixic acid, nitrofurantoin, and sulfa drugs, which can cause hemolysis in G6PD-deficient infants [112]. In general, the severity of the woman's infection, rather than the drug that she is receiving, most often is the more important contraindication to breast-feeding.

## PENICILLIN

Penicillin has been used for treatment of neonatal bacterial infections for more than 3 decades. It is safe and well tolerated. However, efficacy is limited by resistance. Many species of streptococci, *Listeria monocytogenes*, meningococci, and *Treponema pallidum* remain susceptible to penicillin whereas most species of staphylococci, pneumococci, and gonococci have become resistant.

### *Microbiologic Activity*

Penicillin and other β-lactam derivatives interfere with bacterial cell wall synthesis by reacting with one or more penicillin-binding proteins (PBPs) to inhibit transpeptidation [126]. The transpeptidase activity of PBPs is essential for cross-linking adjacent peptides and for incorporating newly-formed peptidoglycan into an already existing strand. Subsequently, this event promotes bacterial cell lysis.

Several mechanisms of bacterial resistance to penicillin and other β-lactams have been identified. The most important is by inactivation through enzymatic hydrolysis of the β-lactam ring by β-lactamases [127]. These enzymes are produced by most staphylococci and enteric gram-negative bacilli and by many *Neisseria gonorrhoeae* strains. Another mechanism of resistance involves decreased

permeability of the outer membrane of gram-negative bacteria, which can prevent this drug from reaching its target site [128]. In addition, by poorly defined mechanisms, some group B streptococci are inhibited but not killed by penicillin, a phenomenon termed tolerance [129]. The first group B streptococcus isolates with elevated MIC to ß-lactamase antibiotics by a mutation in the penicillin-binding protein have recently been described [130]. Usual MICs of penicillin against streptococci are between 0.005 and 0.1 μg/mL. For *T. pallidum*, the corresponding concentration ranges are between 0.02 and 0.2 μg/mL. Many pneumococcal strains isolated around the world are considered to be relatively (MICs of 0.1 to 1 μg/mL) or highly (MICs of 2 μg/mL or greater) resistant to multiple antibiotics, including penicillins, macrolides, and third-generation cephalosporins [131].

## Pharmacokinetic Data

Most of the penicillin dose is excreted in the urine in unchanged form. Tubular secretion accounts for approximately 90% of urinary penicillin, whereas glomerular filtration contributes the remaining 10%. Biliary excretion also occurs, and this may be an important route of elimination in newborns with renal failure.

### Aqueous Penicillin G

A mean peak serum concentration of 24 μg/mL (range, 8 to 41 μg/mL) is observed after a dose of 25,000 units/kg of penicillin G is given intramuscularly to infants with birth weights of less than 2000 g [132]. The peak values do not change appreciably with increasing birth weight or chronologic age up to 14 days. After a dose of 50,000 units/kg, peak serum values of 35 to 40 μg/mL were detected in neonates of different ages. The concentrations at 4 and 8 hours after the dose were not substantially different from those after a dose of 25,000 units/kg. The half-life of penicillin in serum becomes longer in smaller and younger infants. Half-life values of 1.5 to 10 hours are observed in the first week of life; the longer half-lives are in smallest infants with birth weights less than 1500 g. A shorter half-life of 1.5 to 4 hours was observed after 7 days of age. The half-life of penicillin also decreases as creatinine clearance improves.

### Procaine Penicillin G

In the first week after birth, a 50,000 unit/kg intramuscular dose of procaine penicillin G produces mean serum values of 7 to 9 μg/mL for up to 12 hours and a 24-hour trough concentration of 1.5 μg/mL [132]. Older neonates have lower 24-hour trough concentrations, 0.4 μg/mL, due to their increased clearance and shorter half-lives. These serum values are approximately twice those obtained in the original study of 22,000 units/kg, suggesting a linear relationship between dose and serum concentration [133]. No accumulation of penicillin in serum is observed after 7 to 10 days of daily doses of procaine penicillin G. The drug was well tolerated without evidence of local reaction at the site of injection.

### Benzathine Penicillin G

Penicillin can be detected in serum and urine for up to 12 days after a single intramuscular injection of 50,000 units/kg of benzathine penicillin G in newborns. Peak serum concentrations of 0.4 to 2.5 μg/mL (mean, 1.2 μg/mL) are observed 12 to 24 hours after administration, and levels of 0.07 to 0.09 μg/mL are present at 12 days [134,135]. This preparation has been well tolerated by infants. Muscle damage from intramuscular injection as judged from creatinine values does not appear to be appreciably different from that after intramuscular administration of the other penicillins.

## Cerebrospinal Fluid Penetration

Penicillin does not penetrate CSF well, even when meninges are inflamed. Peak concentrations of 1 to 2 μg/mL are measured 30 minutes to 1 hour after an intravenous dose of 40,000 units/kg of penicillin G is given to infants and children with bacterial meningitis [136]. Although these values are 2% to 5% of concomitant serum concentrations, the concentrations exceed the MIC values for streptococci and susceptible pneumococci by 50- to 100-fold. CSF concentrations of penicillin are not optimal to treat neonatal meningitis caused by penicillin-resistant pneumococci. CSF concentrations decrease as meningeal inflammation is reduced. Concentrations of penicillin in CSF during the first several days of therapy are maintained in the range of 0.5 to 1 μg/mL; thereafter, the values are 0.1 μg/mL or less by 4 hours after the dose.

Procaine penicillin G administered by intramuscular injection in newborns provides sufficient CSF exposure for the treatment of congenital neurosyphilis. Procaine penicillin G administered intramuscularly at a dose of 50,000 units/kg provides mean CSF concentrations ranging from 0.12 to 0.7 μg/mL between 4 and 24 hours after a dose [137,138]. These CSF values are at least several fold greater than the required minimum spirocheticidal concentration [139]. Benzathine penicillin G does not provide adequate CSF exposure and is not recommended for the treatment of congenital neurosyphyllis [135].

## Safety

All forms of penicillin are typically well tolerated in newborns. Cutaneous allergic manifestations to penicillin are rare in the newborn and young infant.

## PK-PD and Clinical Implications for Dosing

Penicillin remains effective for therapy for infections caused by group B streptococci and *T. pallidum*. The dosage recommended for neonatal sepsis or pneumonia is 50,000 to 100,000 units/kg per day administered in two to four divided doses, whereas that for meningitis is 250,000 to 450,000 units/kg per day in two to four divided doses, depending on birth weight and chronologic age [140]. The pharmacodynamic target for β-lactam antibiotics is the T>MIC [30]. The trough penicillin concentrations remain above the MIC for streptococci.

Penicillin remains effective therapy for congenital syphilis. However, because central nervous system involvement in congenital syphilis is difficult to exclude with certainty, benzathine penicillin G should not be used for therapy. Its use is acceptable for asymptomatic infants with normal findings on CSF examination and roentgenologic studies, but who have positive results on treponemal serologic studies (presumably from maternal origin),

if follow-up can be ensured. For symptomatic infants, and for asymptomatic infants with laboratory or radiologic evidence suggestive of congenital syphilis, the recommended regimen is either aqueous crystalline penicillin G, 100,000 to 150,000 units/kg daily for 10 to 14 days administered intravenously every 12 hours during the first 7 days of life, and every 8 hours thereafter, for a total of at least 10 days. Alternatively, procaine penicillin G, 50,000 units/kg daily administered intramuscularly for at least 10 days [140].

## Ampicillin

### Antimicrobial Activity

Ampicillin remains the preferred penicillin for initial empirical therapy for neonatal septicemia and meningitis because it provides broader antimicrobial activity without sacrificing safety. Ampicillin is commonly used in combination with aminoglycosides. Compared with penicillin G, ampicillin has increased in vitro efficacy against most strains of enterococci and *L. monocytogenes*, and against some gram-negative pathogens, such as *Haemophilus influenzae*, *Escherichia coli*, *Proteus mirabilis, and Salmonella* species. It is only rarely active against *Staphylococcus aureus*. Approximately 90% of group B streptococci and *L. monocytogenes* organisms are inhibited by 0.06 μg/mL or less of ampicillin. Almost two thirds of the gram-negative enteric bacilli isolated from CSF cultures of infants enrolled in the Second Neonatal Meningitis Cooperative Study (1976 to 1978) were inhibited by 10 μg/mL or less of ampicillin [141]. Recently, however, an increased rate of ampicillin-resistant gram-negative bacilli has been reported and possibly linked to the frequent use of intrapartum prophylaxis with ampicillin to prevent early-onset group B streptococcal neonatal infection [142].

### Pharmacokinetic Data

Ampicillin, similar to many β-lactam antibiotics, is cleared by renal elimination. Therefore, drug clearance and half-life are dependent on renal maturation [10,12,143]. Plasma drug clearance increases (and half-life decreases) with increasing birth weight, gestational age, and chronologic age. Despite its frequent use, the PK of ampicillin in extremely low birth weight infants remains sparse.

Serum ampicillin concentration-time curves have been determined after intramuscular doses in newborns [144–146]. The mean peak serum concentrations 0.5 to 1 hour after 5, 10, 20, and 25 mg/kg doses were 16, 25, 54, and 57 μg/mL, respectively, whereas the values at 12 hours were from 1 to 15 μg/mL (mean, 5 μg/mL). After 50 mg/kg doses, the mean peak values were higher in low birth weight infants (100 to 130 μg/mL) compared with larger term infants (80 to 85 μg/mL). Peak serum concentrations as high as 300 μg/mL (mean values, 180 to 216 μg/mL) are observed 1 to 2 hours after a 100 mg/kg dose [147]. These latter values exceed the $MIC_{90}$ values of group B streptococci by at least 3000-fold. Half-life decreases with advancing age from 3 to 6 hours in the first week of life to 2 to 3.5 hours thereafter.

Serum ampicillin concentration-time curves after intravenous doses have been characterized for preterm and term infants. After a 100 mg/kg intravenous dose, premature infants 26 to 33 weeks gestation had a lower mean peak serum concentration (135 μg/mL) compared with more mature 34 to 40 week infants (153 μg/mL) [148]. When the loading dose was followed by maintenance ampicillin doses of 50 mg/kg intravenously at 12- to 18-hour intervals, the mean peak and trough serum concentrations in steady-state conditions were 113 and 30 μg/mL, respectively, for premature neonates, and 140 and 37 μg/mL for full-term neonates. Despite the lower peak concentration in premature infants, the trough value was maintained likely given the longer half-life in the premature newborn (9.5 hours) compared with full-term newborns (7 hours). Trough values of 30 μg/mL exceed the $MIC_{90}$ value for group B streptococci by 300-fold.

### Cerebrospinal Fluid Penetration

Concentrations of ampicillin in CSF vary greatly. The largest concentrations (3 to 18 μg/mL) occur approximately 2 hours after a 50 mg/kg intravenous dose and exceed the $MIC_{90}$ values for group B streptococci and *L. monocytogenes* by 50- to 300-fold [147]. By contrast, these peak concentrations equal or exceed the MIC values against many *E. coli* strains by only several fold. The values in CSF are lower later in the course of meningitis, when meningeal inflammation subsides.

### Safety

Ampicillin is well tolerated when administered parenterally to newborns. Nonspecific rashes and urticaria are rarely observed, and diarrhea is uncommon. Elevations of serum glutamic-oxaloacetic transaminase and creatinine values frequently are detected in neonates and probably represent local tissue destruction at the site of intramuscular injection. Mild eosinophilia may be noted in newborns and young infants. Alteration of the microbial flora of the bowel may occur after parenteral administration of ampicillin, but overgrowth of resistant gram-negative organisms and *Candida albicans* occurs more frequently after oral administration [149]. Diarrhea usually subsides on discontinuation of therapy.

### PK-PD and Clinical Implications for Dosing

*(See Table 37–11)*

Vast clinical experience has demonstrated that ampicillin is a safe and effective drug for therapy for neonatal bacterial infections caused by susceptible organisms. Combined ampicillin and aminoglycoside therapy is appropriate initial empirical management of suspected bacterial infections of neonates because it provides broad antimicrobial activity and potential synergism against many strains of group B streptococci, *L. monocytogenes*, and enterococci [150–152]. ß-lactam antibiotics exhibit time-dependent killing therefore the PK-PD target is T>MIC [30]. Frequent dosing intervals are used to maintain drug exposure over each dosing interval. For systemic bacterial infections other than meningitis, a dosage of 25 to 50 mg/kg per dose given two to three times a day in the first week of life, and then three to four times a day thereafter, is recommended [153]. For therapy for bacterial meningitis, we recommend a dosage of at least

200 mg/kg per day, although some consultants use dosages as high as 300 mg/kg per day. Premature infants may continue to receive ampicillin 2 to 3 times a day for up to 4 weeks depending on gestational age, chronologic age, and renal function (see Table 37–11).

# ANTISTAPHYLOCOCCAL TREATMENT

*S. aureus* infections occur in nurseries either as sporadic cases or in the form of disease outbreaks. In recent years, multiply-resistant strains, especially methicillin-resistant *S. aureus* (MRSA) and coagulase-negative staphylococcal species such as methicillin-resistant *Staphylococcus epidermidis* (MRSE) have been responsible for an increasing number of nosocomially acquired staphylococcal infections in many neonatal care units.

## Antistaphylococcal Penicillins (Table 37–6)

### *Antimicrobial Activity*

Nafcillin and oxacillin are the mainstays of methicillin-sensitive staphylococcal therapy. These semisynthetic agents are engineered to be resistant to hydrolysis by most staphylococcal β-lactamases by virtue of a substituted side chain that acts by steric hindrance at the site of enzyme attachment. Most penicillinase-producing staphylococci are inhibited by less than 0.5 μg/mL of nafcillin and oxacillin [154].

### *Pharmacokinetic Data (Table 37–6)*

#### Nafcillin

Unlike other penicillins, nafcillin exhibits primarily *hepatic* clearance rather than renal clearance. Only 8% to 25% of this drug is excreted in the urine in a 24-hour period [155]. The administration of 5-, 10-, 15-, and 20-mg/kg intramuscular doses of nafcillin to full-term newborns in the first 4 days of life produces mean peak serum concentrations 1 hour later of 10, 25, 30, and 37 μg/mL, respectively [144,155]. These concentrations are significantly higher than those obtained in older children receiving comparable amounts of this drug [155]. Preterm infants weighing less than 2000 g had higher steady state peak concentrations, 100 to 160 μg/mL, after receiving 33- to 50-mg/kg intravenous doses [156]. In these preterm infants, the half-life ranged from 2.2 to 5.5 hours.

#### Oxacillin

Oxacillin exhibits primarily renal clearance. Despite this difference in clearance mechanism, the PK of oxacillin in neonates is similar to that of nafcillin. Mean peak serum concentrations of approximately 50 and 100 μg/mL are produced by 20- and 50-mg/kg intramuscular doses, respectively [145,157]. The serum half-life of oxacillin in premature infants is about 3 hours in the first week of life and 1.5 hours thereafter.

### *Safety*

The antistaphylococcal penicillins are well tolerated in newborn and young infants. Repeated intramuscular injections can result in muscle damage, sterile muscle abscess, and elevation of creatinine concentrations. Nephrotoxicity (interstitial nephritis or cystitis) is rare in newborns, but occurs in 3% to 5% of children who receive large doses of methicillin and possibly the other antistaphylococcal penicillins, with the exception of nafcillin [158,159]. Reversible hematologic abnormalities such as neutropenia or eosinophilia commonly are observed in children undergoing treatment with these drugs, but their incidence in newborns is unknown [159–162]. Because nafcillin has a predominant biliary excretion, accumulation of this drug in serum can occur in jaundiced neonates, and potential adverse effects can develop. Extravasation of nafcillin at the injection site can result in necrosis of local tissue.

### *PK-PD and Clinical Implications for Dosing (See Tables 37–6, 37–11)*

Nafcillin and oxacillin are the antistaphylococcal drugs most often used for treatment of methicillin-sensitive staphylococcal infections in neonates. Like other ß-lactam antibiotics, it is important to maintain the drug concentrations over the dosing interval (T>MIC). Therefore, as infants mature, drug clearance improves, and dosing intervals shorten. The dosage of oxacillin is 25 to 50 mg/kg every 12 hours (50 to 150 mg/kg per day) in the first week of life and every 6 to 8 hours (75 to 200 mg/kg per day) thereafter. The larger dosage is indicated for infants with disseminated staphylococcal disease or meningitis. For nafcillin, the dosage is 25 mg/kg (50 mg/kg for meningitis) per dose given every 12 hours in the first week of life and every 6 to 8 hours thereafter. Depending on gestational age at birth and chronologic age, extremely preterm infants may have delayed clearance and therefore should continue twice daily dosing for 2 to 4 weeks (Table 37–11). If an infant does not respond to antimicrobial therapy as anticipated, one should consider an occult site of staphylococcal disease (e.g., abscess, osteomyelitis, endocarditis), pathogen resistance, or the need to shorten the dosing interval to maintain time above MIC. Appropriate drainage of purulent foci, addition of an aminoglycoside or rifampin to the regimen, and use of vancomycin are among several options to consider in management of unresponsive infections.

## Methicillin Resistant Staphylococcal Infections (MRSE and MRSA) (See Table 37–6)

MRSA now constitute a relatively common cause of infection outbreaks in some nurseries, and methicillin-resistant *S. epidermidis* (MRSE) strains are an important cause of catheter-associated disease, particularly among low birth weight premature infants. Glycopeptide antibiotics such as vancomycin or teicoplanin (in Europe) are the drugs of choice for infections caused by these resistant strains. Infections may be treated with combination therapy: a glycopeptide with an aminoglycoside or rifampin. More recently, the use of linezolid, clindamycin, and daptomycin are being explored for the treatment of MRSA infections.

## Vancomycin (See Table 37–6)

### *Antimicrobial Activity*

Vancomycin is bactericidal against most aerobic and anaerobic gram-positive cocci and bacilli but is ineffective against most gram-negative bacteria. The drug interferes

**TABLE 37–6** Drugs Used in Treatment of *Staphylococcus aureus*

with the phospholipid cycle of cell wall synthesis, alters plasma membrane function, and inhibits RNA synthesis [1,163]. There is no cross-resistance between vancomycin and other antibiotics. Synergistic bacterial killing has been demonstrated for vancomycin with aminoglycosides.

### Pharmacokinetic Data *(See Table 37–6)*

Vancomycin is not metabolized by the body and is excreted unchanged in the urine by glomerular filtration [1]. Vancomycin clearance reflects renal maturation and increases with gestational and chronologic age. Vancomycin is approximately 55% protein bound.

The PK of vancomycin has been studied in preterm and term infants. Vancomycin clearance improves and elimination half-life shortens with gestational age and chronologic age. Serum creatinine remains an important predictor of renal clearance, even after gestational age and postchronologic age are accounted for. Although vancomycin and gentamicin exhibit similar changes in drug clearance with renal maturation, vancomycin clearance is more delayed likely due to protein binding.

In the first week after birth, peak concentrations of 17 to 30 μg/mL are produced at the end of a 30-minute infusion of a 15-mg/kg dose given to neonates weighing less than 2000 g. Slightly higher values are observed in larger infants. In infants up to 12 months of age, doses of 10 mg/kg produce similar peak serum concentrations.

Population PK studies have attempted to explain the observed variability of vancomycin with chronologic age, maturity, and renal function. In the largest population PK study of 1103 vancomycin concentrations from 374 newborns and infants less than 2 years of age, creatinine levels were strongly correlated with vancomycin elimination, while chronologic age and prematurity (<28 weeks) were significant but less important predictors of vancomycin clearance [164]. Vancomycin clearance for a typical 27 day old, 1.8 kg, ex-33 week gestational age infant with a creatinine of 0.6 mg/dL is estimated to be 0.10 to 0.12 L/hr [164–166]. The volume of distribution (0.5 to 0.8 L/kg) varies with weight and is larger than that reported in older children.

Traditional and population PK studies consistently report improved clearance and shorter half-lives with advancing gestational age and chronologic age [164–171]. The half-life decreases from 6 to 7 hours in the first week of life, to 4 hours in early infancy, then to 2 to 2.5 hours in childhood. In preterm infants, serum half-life of vancomycin is prolonged and variable. The half-life in 1-month old premature infants who weighed less than 1000 g at birth is approximately 10 hours; older premature infants have shorter half-lives of approximately 4 to 5 hours [167,168].

Neonates undergoing extracorporeal membrane oxygenation (ECMO) receiving vancomycin have a larger volume of distribution, lower clearance, and longer half-life [172–175]. However, since infants on ECMO typically have renal insufficiency, some of the delayed vancomycin clearance may be explained by elevated serum creatinine [164].

Vancomycin does not readily penetrate the CSF unless the meninges are inflamed. The CSF concentrations of vancomycin are 10% to 15% of the concomitant serum concentrations in infants with minimal meningeal inflammation, for example, as seen in ventriculoperitoneal shunt infections [176]. The degree of CSF penetration of vancomycin is similar to that for nafcillin. In premature infants born at 26 to 31 weeks of gestational age, dosages of 20 mg/kg every 18 to 24 hours were associated with CSF vancomycin concentrations of 2.2 to 5.6 μg/mL, 26% to 68% of their corresponding serum values [177].

### Safety

Initial experience with vancomycin in the 1950s suggested a moderate incidence of ototoxicity and nephrotoxicity. These adverse effects were presumably related to the impurities found in early preparations of the drug [178]. Further studies have indicated that vancomycin is well-tolerated and safe when administered intravenously, particularly in newborns and young infants [176,179]. Rare cases of ototoxicity and nephrotoxicity typically involved excessive doses, underlying hearing loss or renal disease, and concomitant therapy with other ototoxic or nephrotoxic agents [180]. To minimize risk of nephrotoxicity or ototoxicity, vancomycin trough levels are monitored in patients with underlying renal dysfunction or those receiving concomitant therapy with aminoglycoside [181,182]. Renal function should be monitored during vancomycin therapy. After rapid administration, some patients develop a histamine reaction characterized by an erythematous pruritic rash that can persist for several hours but tends to resolve with antihistamine medications. Use of a slower infusion rate (i.e., over 45 to 60 minutes) usually avoids this adverse event. Vancomycin is irritating to tissue and is thus always administered through the intravenous route.

### PK-PD and Clinical Implications for Dosing *(See Tables 37–6, 37–11)*

The primary indication for vancomycin therapy in newborns is for infections caused by MRSA and by ampicillin-resistant enterococci. Vancomycin is the initial drug of choice for documented infections caused by *S. epidermidis* because most strains are resistant to penicillin, methicillin, cephalosporins, and aminoglycosides. The rate of killing of staphylococci is slow for vancomycin compared with β-lactams. If susceptibility data for staphylococcal infections reveals methicillin sensitivity, then the antibiotic regimen should be adjusted. For β-lactam sensitive staphylococci and enterococci, vancomycin was inferior to nafcillin and ampicillin when comparing bactericidal rate and rapidity of blood sterility [183,184].

Vancomycin is a concentration-independent, time-dependent antibiotic with moderate postantibiotic effect (PAE) [185]. The continued suppression of bacterial growth against gram-positive bacteria can persists for several hours depending on the organism and initial antibiotic concentration, typically ranging from 0.6 to 2 hours for *S. aureus* and 4 to 6 hours for *S. epidermidis* [186]. Both increased AUC/MIC and increased Time>MIC have been shown to promote bacterial clearance [187,188]. MRSA and *S. epidermidis* are typically sensitive to vancomycin with MIC<2 mg/L. Serum bactericidal titers of 1:8 (approximate serum concentrations of 12 mg/L) have

been associated with clinical cures in children [176]. Animal models of endocarditis have correlated outcome with trough serum concentrations [189]. In these studies, the vancomycin concentrations exceed the MIC for 100% of the dosing interval, bactericidal activity was maintained [190]. Bactericidal activity has also been shown when vancomycin trough concentrations were greater than 10 mg/L [191]. Keeping the trough level above the MIC is likely to be necessary for effective vancomycin treatment.

Several vancomycin dosing regimens have been proposed [164,165,192]. Traditional dosage schedule for vancomycin in neonates is typically 10 to 15 mg/kg every 12 hours (20 to 30 mg/kg/day) in the first week of life and every 8 hours (30 to 45 mg/kg/day) thereafter. Extremely premature infants have unique dosing requirements to account for changes in body water composition and postnatal maturation in renal function. Recently, analysis of population PK studies suggest that vancomycin dosage can be dependent on serum creatinine and independent of postmenstrual age [164]. Beyond the newborn period, daily administration of 40 to 60 mg/kg (divided into three or four doses) is recommended. The larger dosage (15 mg/kg) is used for treatment of central nervous system infection or pneumonia.

Historically, vancomycin dosing has been designed to achieve peak serum concentrations between 20 to 40 mg/L and serum trough concentrations of 5 to 10 mg/L. In light of advances in our understanding the PK-PD relationship for vancomycin, peak levels are rarely useful since they are not associated with efficacy [192]. There is no clear relationship between peak concentration and nephrotoxicity, except possibly when peak levels exceed 60 mg/L [181,182]. The relationship between serum levels and efficacy or toxicity have not been determined in neonates.

Therapeutic drug monitoring is now focused on trough serum concentrations to optimize PK-PD efficacy targets. Trough values of at least 10 ensure that the non-protein-bound vancomycin concentration will typically remain above the MIC of the offending organism. Many infectious disease experts advocate for higher trough concentrations (i.e., 10 to 20 μg/mL, when treating serious MRSA infections) [193,194]. The safety of these higher exposures has not been evaluated in children. Extremely preterm infants, infants with renal insufficiency or variable renal function, and infants on ECMO are likely to need more frequent monitoring.

The dramatic increase in worldwide prevalence of vancomycin-resistant enterococci (VRE) and the serious threat posed by the spread of vancomycin resistant staphylococci has discouraged the use of vancomycin for antimicrobial prophylaxis or empirical therapy.

## Linezolid (See Table 37–6)

### Antimicrobial Activity

Linezolid is a synthetic oxazolidinone antibiotic that inhibits bacterial protein synthesis in a broad range of gram-positive organisms [1,195–198]. In kill curve experiments, linezolid is bacteriostatic against staphylococci and enterococci but can be bacteriocidal against streptococci [199–201]. Linezolid has a unique mechanism of action and therefore does not exhibit cross-resistance with antistaphylococcal penicillins or vancomycin. It is FDA-approved for treatment of infections caused by glycopeptide-resistant strains of *Enterococcus faecium*, *S. aureus*, and *S. pneumoniae* in neonates [1,195,196].

### Pharmacokinetic Data (Table 37–6)

Linezolid is known for its rapid and nearly complete absorption after oral dosing [1,195]. Bioavailability is approximately 100% in adults but has not been well characterized in neonates. Only 30% of linezolid is eliminated via the kidneys as active drug in the urine. Nonrenal pathways account for approximately 65% of total body clearance for linezolid. Linezolid is oxidized on the morpholine ring resulting in two inactive metabolites that are then excreted in the urine. The specific biotransformation pathways in children have not been defined. Linezolid is not a cytochrome P450 substrate. Single dose PK for intravenous linezolid has been assessed in 42 neonates (25 to 40 weeks of gestation) in the first 80 days of life [202–204]. Linezolid clearance increases rapidly in the first week of life and is relatively constant from day 8 to 79 after birth. The increases in clearance are likely related to the development of biotransformation pathways after birth and age associated increases in glomerular filtration for the residual renal elimination of the drug. Linezolid volume of distribution varies inversely with gestational age. In the first week of life, preterm infants have a slower clearance and longer half-life (2.0 (mL/min)/kg and 5.6 hours) compared with more mature infants (3.8 (mL/min)/kg and 3 hours). Beyond the first week of life, clearance and half-life estimates are similar (5.1 (mL/min)/kg and 1.5 hours) in preterm and term infants up to 90 days of age. Linezolid trough concentrations at 11 hours are 0 to 4 μg/mL. Infants receiving 10 mg/kg dose are predicted to have a mean area under the concentration curve (AUC) of 54.9 mg*h/L. Infants have faster clearance and shorter half lives than older infants such that infants (>7 days old) dosed every 8 hours achieve similar AUC as older children. CSF penetration by linezolid is inconsistent; children with ventricular peritoneal shunts receiving the drug did not consistently achieve or maintain therapeutic concentrations in the CSF. In adults, moderate hepatic or renal insufficiency does alter the pharmacokinetics of linezolid. The drug's metabolites accumulate in adults with renal insufficiency; however, the clinical significance of these metabolites is unknown.

### Safety

Linezolid has been well tolerated in the small number of infants and children in PK and efficacy trials. In pediatric comparator trials, the most common drug-related adverse events in children treated with linezolid were diarrhea, nausea, vomiting, anemia, and thrombocytopenia [205–207]. Drug-related adverse events rarely led to discontinuation of therapy. Linezolid is a reversible, nonselective inhibitor of monoamine oxidase [1,196]; therefore, it has the potential for interaction with adrenergic and serotonergic agents. Patients receiving linezolid may have an enhanced pressor response to sympathomimetic agents including dopamine. Myelosuppression has been reported and therefore complete blood counts should be monitored weekly in patients on linezolid therapy, particularly

for therapy beyond 2 weeks [1,196]. One noncomparative study found good therapeutic outcomes, but a high rate of adverse reactions, in adults with serious gram-positive infections treated with linezolid for a mean of 28 days [208].

### PK-PD and Clinical Implications for Dosing

*(See Tables 37–6, 37–11)*

Linezolid is indicated for the treatment of vancomycin resistant *E. faecium* (VRE) infections, pneumonia due to MRSA or *S. pneumoniae*, and severe, complicated skin infections due to susceptible organisms [197,198]. Linezolid penetrates respiratory secretions and epithelial lining fluid better than vancomycin [209]. Linezolid exhibits time-dependent killing with moderate to prolonged persistent antimicrobial effects [201]. The primary PD determinant associated with efficacy in the neutropenic thigh infection model for *S. pneumoniae* and *S. aureus* is an AUC/MIC ratio of 50 and 80, respectively [210]. Susceptible strains of *Enterococcus* and *Streptococcus* species have MIC of 2 μg/mL, whereas the susceptible strains of staphylococci have MIC of 4 μg/mL. In adults with MRSA or VRE favorable outcomes were experienced in 97% of those who achieved a linezolid AUC/MIC ratio of greater than 95 compared with 75% of those who had lower AUC/MIC ratios [211]. Administration of continuous linezolid infusions, such that drug concentrations are maintained above the MIC for entire dosing interval, has been associated with bacteriocidal activity [212,213]. For adults with MRSA infections, there appears to be no significant difference in clinical cure or microbiologic cure between linezolid and vancomycin [214]. However, linezolid was superior to vancomycin in one adult comparator trial of complicated skin and soft tissue infections [215].

Linezolid clinical trials have been performed in hospitalized young infants and children with documented gram-positive infections [195,206,216]. Linezolid was well tolerated at a dosage of 10 mg/kg every 8 hours and as effective as vancomycin for treatment of resistant gram-positive infections. Infants require dosing every 8 hours to maintain AUCs similar to those achieved in adolescents and adults dosed every 12 hours [1,196]. An AUC of 100 would achieve AUC/MIC ratios of 50 if the MIC of organism was 2, as would be expected for most enterococcal or streptococcal infections. Higher doses may be needed to achieve this AUC/MIC target in infants with faster drug clearance or infants with MRSA infections where the MIC may be between 2 to 4 μg/mL; PD targets have not been confirmed in clinical trials. In the first few days of life, infants may accumulate linezolid as clearance is rapidly changing. For extremely preterm infants younger than 7 days of chronologic age, we would consider a dose of 10 mg/kg every 12 hours [153,195]. The risk of drug accumulation is balanced with the need to rapidly achieve and maintain adequate plasma and tissue concentrations of drug during a developmental period of rapidly improving clearance. The potential for linezolid resistance has been documented; further emergence and spread of such resistance may depend on its prudent use.

## Clindamycin (See Table 37–6)

### Antimicrobial Activity

Clindamycin replaced its parent compound lincomycin because it is more completely absorbed from the gut, has fewer adverse effects, and has greater antibacterial activity in vitro [1,217,218]. Clindamycin is primarily a bacteriostatic agent that acts by inhibiting protein synthesis through reversible binding to bacterial ribosomes, thus inhibiting bacterial protein synthesis. Clindamycin is active against gram-positive cocci such as *S. aureus*, *S. pneumoniae* (including many multidrug-resistant strains), and *Streptococcus pyogenes*. It also maintains notable activity against anaerobic bacteria, especially members of the *Bacteroides* group. Aerobic gram-negative bacteria are not usually susceptible to this antibiotic. Resistance to clindamycin appears to be related to alterations of its target site and not to reduced uptake or to breakdown of the drug by the resistant bacteria.

### Pharmacokinetic Data

Clindamycin pharmacology has been recently reviewed; however there is a paucity of information in neonates [1,217,218]. Clindamycin exhibits significant (94%) protein binding. The drug is eliminated primarily by the liver, with only about 10% excreted in unchanged form in the urine. Clindamycin is reported to be a cytochrome P-450 substrate that may increase the neuromuscular blocking action of tubocurarine and pancuronium. Clindamycin has been shown to accumulate in patients with hepatic dysfunction. It is widely distributed throughout the body including pleural fluid, ascites, bone, and bile. However, no significant levels (~20%) are seen in the CSF, even in setting of meningitis. Experimental meningitis animal models have demonstrated CSF penetration after parenteral administration [219]. In adults, clindamycin exhibits excellent bioavailability after oral administration.

When intravenous clindamycin was administered to infants in the first 4 weeks after birth, in a dosage schedule of 6.5 mg/kg every 8 hours (preterm) or 5 mg/kg every 6 hours (term), the mean peak serum concentrations was 10 μg/mL and trough values ranged from 2.8 to 5.5 μg/mL [220]. The serum elimination half-life was inversely related to gestational age and birth weight. Premature neonates demonstrated a mean serum half-life of 8.7 hours, compared with 3.6 hours for term newborns [220]. Another study of 12 neonates demonstrated a serum elimination half-life of 3.5 to 9.8 hours (mean, 6.3 hours) [221]. Neonates have longer elimination half-lives for clindamycin than the 3 hour half-life observed in infants 1 month to 1 year.

### Safety

Adverse effects of clindamycin include diarrhea, rashes, elevated levels of hepatic enzymes, granulocytopenia, thrombocytopenia and, rarely, Stevens-Johnson syndrome. The most serious potential complication to consider is pseudomembranous colitis. Many asymptomatic neonates are colonized with *C. difficile*, the presumed etiologic agent of pseudomembranous colitis [222]. However, evidence for an association of *C. difficile* colonization with colitis in newborns is lacking and pseudomembranous

colitis is rare in both newborns and young infants. This adverse effect also is observed with the use of ß-lactam and other antimicrobial agents.

### PK-PD and Clinical Implications for Dosing

*(See Tables 37–6, 37–11)*

Recent clinical information suggests that clindamycin can be effectively used to treat MRSA infections [223–225]. Caution is advised, however, because resistance to clindamycin can be induced after selective antimicrobial pressure, particularly in MRSA organisms that initially are clindamycin-susceptible and erythromycin-resistant. Use of clindamycin in selected MRSA-infected newborn patients can obviate the need for vancomycin therapy. For treatment of the rare *B. fragilis* infections in newborns, especially those involving the central nervous system, metronidazole or clindamycin have been used. Clindamycin is said to have poor penetration into the CSF [226] albeit good penetration into brain tissue [227].

Considerable debate exists regarding the optimal dose of clindamycin. Antibacterial activity is concentration-independent and time-dependent with considerable post-antibiotic effect [185,228]. Clindamycin has antibacterial activity that appears to be maximized as drug concentrations approach 1 to 4 times the MIC and also has a considerable postantibiotic effect (4 to 6 hours) [229–231]. In the murine thigh infection model, clindamycin has been effective against clindamycin-susceptible (and noninducible) MRSA [232]. One proposed PK-PD target is to maintain the clindamycin concentration above the MIC for 50% of the dosing interval. Most staphylococcal species have a low MIC (<1 mg/L) for the drug. Much lower dosing than is currently used in adults was shown to achieve equivalent killing and maintain the clindamycin concentration above the MIC for 100% of the dosing interval [229]. Empirical dosing information based upon the limited PK information available is 5 mg/kg/dose administered every 12 hours in the first week of life and every 6 to 8 hours thereafter. Preterm infants may have decreased clindamycin clearance, therefore dosing interval is typically maintained at 8 to 12 hours for the first 2 to 4 weeks after birth. These doses are less than recommended in infants and young children (25 to 40 mg/kg/day divided every 6 to 8 hours). More neonatal PK data is needed, especially in extremely low birth weight infants with serious bacterial infections in the first 90 days after birth. Because clindamycin is highly protein bound, assays need to clearly quantify the molecularly active nonprotein bound exposure to clindamycin.

## Rifampin

In selected neonates with persistent, systemic staphylococcal infections, rifampin has been used to provide a synergistic effect when given with other antistaphylococcal drugs [1,233–237]. Resistance rapidly emerges with rifampin monotherapy. In adults, rifampin is widely distributed throughout the body including the CSF [1,238–240]. Rifampin is 80% protein-bound and is eliminated in bile after progressive deacetylation to metabolites that remain microbiologically active. No dose adjustment is needed for renal insufficiency. Rifampin is bacteriocidal through the inhibition of bacterial-specific DNA-dependent RNA polymerase activity. It is active against most strains of *Neisseria meningitidis*, *Mycobacterium tuberculosis*, and aerobic gram-positive bacteria including MSSA, MRSA, and *S. epidermidis*. Safety concerns regarding rifampin are focused on thrombocytopenia, liver dysfunction and jaundice; liver function and blood count monitoring is recommended. Rifampin has been found to compete with bilirubin for biliary excretion and increased bilirubin has been observed. Rifampin is also known to induce cytochrome P-450 enzymes and therefore drug interactions are possible [241]. Rifampin has been shown to accelerate elimination of drugs that are used in the neonatal population, including phenytoin, azole antifungal agents, narcotic analgesics, diazepam, and corticosteroids.

Neonatal PK information for intravenous rifampin is sparse and dosing remains empiric [234,237,242,243]. In one small study, infants (mean age of 23 days) received rifampin 10 mg/kg/day and had a mean peak concentration of 4.02 μg/mL and a mean 12-hour trough concentration of 1.11 μg/mL [243]. In children, rifampin clearance is induced after 8 days of therapy. As rifampin clearance increases and half-life decreases, the dosing interval may need to be shortened to accommodate induced clearance in prolonged therapy [244]. Uncontrolled clinical case series suggest that rifampin used as an adjunct to vancomycin therapy can provide prompt clearance of persistent staphylococcal bacteremia or ventriculitis in high risk neonates [234,237,242,243].

## Teicoplanin

Teicoplanin is a glycopeptide antibiotic that is almost identical to vancomycin with regard to its antibacterial spectrum of activity. It is used frequently in Europe where it is approved for the treatment of gram-positive infections [245,246]; however, it is not approved for use in the United States. Teicoplanin may have some advantages over vancomycin in terms of tolerability, with a lower propensity to cause nephrotoxicity and histaminic-type reactions. Teicoplanin also has a longer elimination half-life allowing for longer dosing intervals. It rapidly penetrates into tissue and reaches high concentrations in the kidney, trachea, lungs, and adrenals but does not penetrate well into the cerebrospinal fluid. It is excreted unchanged in the urine after a prolonged elimination phase.

Despite these potential advantages, teicoplanin PK data adequate to formulate dosage regimens in neonates are lacking. In one study, four neonates received a single dose of 6 mg/kg, and the mean peak serum teicoplanin concentration was 19.6 μg/mL, with a mean half-life of 30 hours [247]. In several noncomparative trials, the clinical and bacteriologic response rates ranged between 80% and 100% in 173 infected neonates given teicoplanin 8 to 10 mg/kg intravenously once daily, after a loading dose of 10 to 20 mg/kg [248]. A recent study of 37 episodes of staphylococcal bacteremia in neonates treated with a loading dose of 16 mg/kg teicoplanin followed by a maintenance dose of 8 mg/kg/day achieved bacterial eradication in 89% and survival of 94% with no documented drug-related adverse events [249]. One neonate was reported to have tolerated teicoplanin overdose (20 mg/kg/day for 5 days) [250].

## Daptomycin

Daptomycin is the first-in-class of the cyclic lipopeptide family [251–254]. Lipopeptides have a unique mechanism of action. They insert into bacteria membranes and cause a rapid membrane depolarization leading to inhibition of protein, DNA and RNA synthesis, cell leakage, and ultimately cell death. Daptomycin exhibits rapid, concentration-dependent, bacteriocidal activity against MRSA, MRSE, vancomycin-resistant *S. aureus*, and VRE. The product is approved in the United States for the treatment of complicated skin and skin structure infections, and *S. aureus* bacteremia [232,251,255–258]. Daptomycin is not indicated for the treatment of pneumonia due to its inactivation by surfactant [259]. Daptomycin exhibits a high degree of protein binding, and is primarily excreted unchanged by the kidney. In clinical trials, a few adults receiving daptomycin had elevated creatine phosphokinase (CPK) enzyme and, rarely, myopathy [251,260]. The manufacturer recommends monitoring CPK weekly while on therapy and discontinuing therapy for myopathy, myalgia, or CPK greater than 1000 mg/dL [251].

Daptomycin is not approved for use in children or neonates. One single dose PK study in 25 children with suspected or proven gram-positive infections revealed more rapid clearance in younger children with adolescents [261]. Two infants with complicated MRSA infections who received 6 mg/kg dose every 12 hours had peak and trough concentrations that were consistent with concentrations observed in adults treated with a 4 mg/kg daily dose [262]. These infants achieved microbiologic and clinical cure; however, their exposure was less than that achieved in adults receiving daptomycin at the approved dose of 6 mg/kg/day for treatment of MRSA bacteremia.

# AMINOGLYCOSIDES (See Table 37–7)

## History

For more than 3 decades, the aminoglycosides have been relied upon for therapy for neonatal sepsis because of their broad-spectrum antibacterial activity against gram-negative bacilli. However, their use in some centers is decreasing because of the emergence of resistant strains. Currently, gentamicin, tobramycin, and amikacin are the aminoglycosides of choice in most nurseries. Because amikacin is resistant to degradation by most of the plasmid-mediated bacterial enzymes that inactivate gentamicin and tobramycin, some centers have held amikacin in reserve for treatment of nosocomially acquired infections due to multidrug-resistant gram-negative organisms. Gentamicin resistance occurs frequently enough in some European, Latin American, and U.S. centers to warrant use of amikacin as a first-line drug for therapy of life-threatening gram-negative infections. Thus far, its routine use has not resulted in emergence of resistant strains.

The history of aminoglycoside usage in the late 1950s and 1960s is an excellent example of the inherent problems of adapting dosages derived from studies in adults to newborns. Irreversible ototoxicity in neonates was caused by excessive doses of streptomycin or kanamycin. By contrast, the PK of gentamicin, tobramycin, amikacin, and netilmicin were carefully defined in the neonate before routine use of these drugs; appropriate studies thus provided a scientific basis for safe and effective dosage regimens. The risk of aminoglycoside toxicity is minimal when these agents are administered to infants in the proper dosage and when serum concentrations are closely monitored and kept within the recommended therapeutic range.

The evolution of gentamicin dosing over recent years is also an excellent example of dosing modifications that target PD to achieve optimal therapeutic exposure. Aminoglycoside administration using extended dosing intervals appears to be at least as safe and effective as giving these drugs in two or three divided doses. The extended dosing interval schedule provides a higher peak concentration to maximize the concentration-dependent bacterial killing and take advantage of the prolonged postantibiotic effect (PAE) of the aminoglycosides [263–265].

### *Antimicrobial Activity*

Aminoglycosides act on microbial ribosomes to irreversibly inhibit protein synthesis. In general, gentamicin, tobramycin, and amikacin have good antibacterial activity against most gram-negative strains isolated in many hospitals worldwide. Tobramycin has the greatest antipseudomonal activity [266], while amikacin is the only drug of this class that reliably provides activity against *Serratia* species and other coliforms with nosocomially-acquired resistance. Although staphylococci are susceptible in vitro to aminoglycosides, infections caused by these pathogens usually do not respond satisfactorily to aminoglycoside therapy alone. Synergistic bactericidal activity between aminoglycosides and the penicillins has been demonstrated in vitro and in animals against *S. aureus* [267], group B streptococci [268,269], *L. monocytogenes* [151], and enterococci [152], in spite of low-level resistance of each microorganism to the aminoglycoside alone.

Possible mechanisms of bacterial resistance to these drugs include alteration of the ribosomal binding site, changes in the cell surface proteins to prevent entrance of drug into the cell, and induction of aminoglycoside-inactivating enzymes. Antibiotic resistance in clinical situations is most often a result of extrachromosomally controlled (R-factor) enzymes. Phosphorylation, adenylation, and acetylation are the three most common enzymatic mechanisms encountered [270–272]. High concentrations of aminoglycosides may reduce the emergence of resistance by targeting resistant subpopulations.

Some gram-negative organisms, notably *Pseudomonas aeruginosa* and *Enterobacter* species, demonstrate reduced uptake of aminoglycosides after initial exposure [273,274]. Such reduced uptake can decrease bacterial killing and is referred to as adaptive resistance; it may last for several hours after initial antibiotic exposure but appears to be reversible after a duration of low plasma aminoglycoside concentrations [275].

### *Pharmacokinetic Data* (*See Table 37–7*)

#### Gentamicin

Gentamicin is the most methodically studied aminoglycoside in newborns; however, there is considerable interpatient variability in gentamicin concentrations achieved in neonates. This variability is typically due to changes in renal function and body water composition with

**TABLE 37–7** Aminoglycosides and Aztreonam for the Treatment of Gram-negative Infections

| Drug | Route of Elimination | Peak µg/mL | Half-life (hours) | PK:PD Target | Protein Binding %0 | CSF%[‡] | CLSI MIC[§] *E. coli, Klebsiella* | CLSI MIC[§] *P. aeruginosa* | Safety and Clinical Pearls |

advancing gestational age, chronologic age, and creatinine clearance [276–292].

Gentamicin is administered via intramuscular or intravenous injection. Early PK studies of gentamicin demonstrated that the serum concentration-time curves after an intramuscular injection and after a 20-minute intravenous infusion were nearly superimposable [276,293]. Aminoglycosides such as gentamicin cannot be administered orally for treatment of systemic infection because they are not absorbed from the intact gastrointestinal tract [294].

Analysis of peak and trough concentrations reveal significant interpatient variability within and between studies. Recent clinical trials have compared gentamicin concentrations using traditional and extended-interval dosing regimens in primarily term and near-term neonates in the first week after birth: traditional 2.5 mg/kg dosing is associated with mean peak concentrations of 6.5 μg/mL and 12-hour trough concentration near 2 μg/mL [295–297]; extended interval regimens of 4, 5, or 8 mg/kg dosing yields peak concentrations of 8, 10, and 11 μg/mL, respectively, and 24-hour trough concentrations near 1 μg/mL for the 4 to 5 mg/kg regimen and “next day” trough values of 0.3 to 6.2 μg/mL for the 8 mg/kg regimen [295–299,300].

Neonates have reduced gentamicin clearance and increased volume of distribution compared with older patients. Neonatal population PK studies of gentamicin have attempted to explain the variability of gentamicin disposition with demographic and clinical variables [301–305]. Volume of distribution is consistently associated with infant weight and ranges from 0.45 to 0.69 L/kg. The mean relative clearance is between 0.04 to 0.06 (L/h)/kg typically depending on how many premature infants were included in the model and their chronologic age. Clearance improves with advancing gestational age, chronologic age, postmenstrual age, and creatinine clearance as expected for improved renal maturation [305]. Extended dosing intervals are often warranted in extremely premature infants and those with elevated creatinine or decreased urine output. In a traditional dosing regimen (2.5 mg/kg/dose), preterm infants often required 18 to 24 hour dosing intervals to achieve trough concentrations less than 2 μg/mL [281,287,306–309].

The serum half-life of gentamicin is longer in younger, smaller, more immature infants and those with reduced creatinine clearance [276,278,280,281,285,286]. During the first week of life, very low birth weight (800 to 1500 g) infants have long gentamicin half-lives, up to 14 hours, compared with 4.5 hours in term infants. More recent studies have reported elimination half lives of 8 to 9 hours in the first week after birth, and 5 hours in 12- to 24-day-old infants [303,304]. Both perinatal asphyxia and patent ductus arteriosus (or its treatment) are associated with prolonged serum gentamicin half-life likely due to decreased renal clearance [291,310].

CSF concentrations of gentamicin in infants with meningitis are from 0.3 to 3.7 μg/mL (mean, 1.6 μg/mL) 1 to 6 hours after a 2.5-mg/kg dose [141]. Peak values are observed 4 to 6 hours after the dose and are correlated with the degree of meningeal inflammation and dosage. During the 1970s, the Neonatal Meningitis Cooperative Study Group evaluated lumbar intrathecal and intraventricular gentamicin administration in comparative studies with systemic antibiotic therapy alone [141]. Despite higher CSF and intraventricular fluid concentrations, neither route of administration of therapy was associated with a better outcome in infants with meningitis caused by gram-negative enteric organisms. In fact, case-fatality rates were significantly greater in intraventricular gentamicin recipients. Poor outcomes may in part be explained by the rapid lysis of gram-negative bacteria associated with high ventricular fluid gentamicin concentrations, the subsequent release of significantly larger amounts of endotoxin into the ventricular fluid, and greater meningeal inflammation [311].

Serum concentrations are altered by exchange transfusion and ECMO; after a two volume exchange transfusion, serum aminoglycoside concentrations are reduced by 19% to 62% [312,313]. Whenever possible, such procedures are best timed to precede the next scheduled dose of gentamicin. Therapeutic drug monitoring is needed to guide dosing for infants on ECMO because gentamicin, and probably other aminoglycosides, exhibit a higher volume of distribution, a lower clearance, and a longer half-life [314].

## Tobramycin

Tobramycin (see Table 37–7) offers two theoretical advantages over gentamicin for therapy for neonatal infections: increased in vitro activity against *P. aeruginosa* and decreased nephrotoxicity [315]. The lower incidence of nephrotoxicity for tobramycin has been documented in laboratory animals and human adults but not in neonates [316]. Because of the relative resistance of neonates to aminoglycoside nephrotoxicity, the applicability of such advantages in young infants is uncertain.

After a 2 mg/kg dose of tobramycin, mean peak serum concentrations of 4 to 6 μg/mL are observed at 30 to 60 minutes [317]. When an identical dose is given to low birth weight neonates, mean peak serum values are 8 μg/mL. Predose trough concentrations are higher in smaller and more premature infants; trough concentrations are often greater than 2 μg/mL in premature neonates receiving 2.5 mg/kg doses every 12 hours [318–320]. The serum tobramycin half-life is also prolonged in smaller, younger, and more premature infants and in those infants with delayed creatinine clearance [317,318,320]. In the first week after birth, very low birth weight infants (<1500 g) have half-life values as long as 9 to 17 hours, compared with values of 3 to 4.5 hours for larger infants (>2500 g) and older infants who are 1 to 4 weeks old. Premature infants born at less than 30 weeks of gestation, often require dosage intervals of 18 to 24 hours [318,320,321]. Therapeutic drug monitoring and individualization of the dosage schedule are often needed to provide the optimal therapy for very low birth weight infants.

## Amikacin

Neonatal amikacin (see Table 37–7) PK data are limited. Mean peak serum concentrations of 15 to 20 μg/mL occur 30 minutes to 1 hour after 7.5-mg/kg doses of amikacin. Mean trough concentrations of 3 to 6 μg/mL are

detected 12 hours after administration [322,323]. Doses of 10 mg/kg at 12-hour intervals were required to achieve a mean peak value of 21.5 μg/mL and a trough concentration of 3.3 μg/mL. By contrast, investigators in another study [324] noted that subtherapeutic serum concentrations of amikacin given to premature infants in 7.5 mg/kg intravenous doses every 12 hours were present in only 10% of infants younger than 2 weeks of age. As many as 38% of infants 29 days of age or older had peak serum concentrations below 15 μg/mL.

Serum half-life of amikacin is longer in younger and more premature infants [322,323]. Half-life values of 7 to 8 hours occur in low birth weight infants 1 to 3 days of age, and half-life values of 4 to 5 hours in term infants who are older than 1 week of age. The serum half-life is prolonged in hypoxemic newborns [28]. More recently, neonatal population PK studies of amikacin have explored the wide variability of disposition. In a study of one day old, preterm and term infants (24 to 41 weeks), amikacin clearance increased with gestational age and volume of distribution increased with body weight [325]. In more mature infants (mean GA 35 weeks) treated with amikacin in the first week of life, clearance and volume of distribution varied with weight [326].

Reports of CSF concentrations of amikacin are scarce [327–330]. In the presence of uninflamed meninges in 1-day-old infants, CSF values ranged from 0.2 to 2.7 μg/mL when measured at 1 to 4 hours after a single 10-mg/kg dose administered by slow intravenous infusion [328]. Simultaneous concentrations in serum ranged from 15 to 29 μg/mL. The highest CSF concentration reported has been 9.2 μg/mL after a 7.5 mg/kg dose was administered intramuscularly to an infant with meningitis [322]. Amikacin concentration in ventricular fluid 12 hours after 1 or 2 mg intraventricular doses and 2 to 8 hours after intramuscular doses varies, ranging from 4.5 to 11.6 μg/mL (mean, 7.3 μg/mL). In the largest and most recent study of 43 preterm and term infants (mean postmenstrual age 36 weeks, range, 26 to 41 weeks) the median amikacin CSF concentration was 1.09 μg/mL (range, 0.34 to 2.65 μg/mL) and the mean peak and trough serum concentration were 35.7 μg/mL and 3.8 μg/mL, respectively [327]. Concentrations in CSF were low likely because the CSF sampling occurred at a median of 25 hour after amikacin administration; no correlation between CSF white blood cell count and CSF amikacin levels was identified.

## Safety

The major adverse effects of aminoglycoside antibiotics are renal toxicity, ototoxicity, and, rarely, neuromuscular blockade [331–334]. Aminoglycosides are eliminated through glomerular filtration, but some drug is reabsorbed in the proximal tubule. Aminoglycosides may accumulate in renal tubular cells where they fuse with cytoplasmic lysosomes and inhibit phospholipases, with the resultant accumulation of phospholipid aggregates and release of lysosomal contents within the renal tubular cells. The potential for nephrotoxicity varies among the aminoglycosides because of differences in the rate of uptake and amount of drug accumulation in the renal cortex. This renal cortical uptake is saturable in rats [335]. Human nephrectomy studies have also demonstrated saturable uptake: higher renal cortical aminoglycoside (amikacin, gentamicin but not tobramycin) concentrations when doses were administered by continuous infusion or twice daily compared with once daily [336,337]. Toxicity is correlated with elevated drug trough concentrations and prolonged therapy, but not with high peak concentrations. Extended aminoglycoside dosing intervals produce longer periods at low drug concentration, thereby lessening the potential for renal drug accumulation and toxicity.

Meta-analysis of adult trials of extended interval aminoglycoside administration compared with conventional multidose daily administration showed that the rate of nephrotoxicity with extended interval dosing was less than or equal to that observed with traditional regimens [338–344]. In addition to drug dose and administration regimen, the risk factors for nephrotoxicity also include the concomitant medications and the patient's clinical condition.

The reported incidence of aminoglycoside nephrotoxicity ranges from 5% to 25% and is thought to be lower in children than adults [334]. It has been suggested that the immature kidney of the neonate may be protected from major toxic effects of aminoglycosides. Transient cylindruria and proteinuria may occur after prolonged administration of any of these drugs, but significant elevations in blood urea nitrogen and creatinine values are rarely observed [345–352]. In neonatal comparative trials of once-daily extended-interval dosing compared with multi-dose standard dosing of aminoglycosides, nephrotoxicity was rare and there was no significant difference noted between the two dosing administration groups [339]. Because renal excretion accounts for the elimination of approximately 80% of an aminoglycoside dose, the risk of toxicity is greatest when drug elimination is impaired by reduction in renal function for any reason. Therapeutic drug monitoring is often helpful in neonates. The criteria of maintaining peak and trough serum aminoglycoside concentrations within recommended values for older children and adults to prevent nephrotoxicity [353] have not been systematically assessed in newborns and should be considered as a guide rather than an established rule for formulating dosages of aminoglycosides in this age group. Factors that may be associated with increased risk for aminoglycoside nephrotoxicity include acidosis, hypovolemia, hypoalbuminemia, sodium depletion, duration of therapy, increased total aminoglycoside dose, and frequency of administration and co-administration of furosemide, vancomycin, or prostaglandin synthesis inhibitors such as indomethacin [348,350,354,355].

Neomycin [356,357], streptomycin [358], kanamycin [359], and gentamicin [141] each have been implicated as a cause of sensorineural hearing loss in infants and children. Gentamicin and streptomycin also have been associated with vestibular impairment. However, it is difficult to incriminate the aminoglycosides as the single causative agent of hearing loss in most studies because of the high-risk conditions present in affected patients such as asphyxia, hyperbilirubinemia, and incubator/ventilator noise exposure that have been independently associated with ototoxicity [360]. Although animal studies have demonstrated a synergistic effect of noise combined

with neomycin or kanamycin administration on development of ototoxicity, such an effect has not been substantiated in the human neonate exposed to both incubator noise and kanamycin [360,361].

In a prospective evaluation of long-term toxicity of kanamycin and gentamicin, neither was incriminated as the sole agent responsible for hearing impairment [362]. Ototoxicity has been related primarily to very high total aminoglycoside dosages: high-frequency sensorineural hearing loss in infants with normal renal function is more likely if the total dosage exceeds 500 mg/kg [362]. Data from the first Neonatal Meningitis Cooperative Study [141] indicated that profound deafness potentially related to gentamicin exposure developed in only 1 (1.3%) of 79 infants who received a minimum of 5 to 7.5 mg/kg/day of the drug for 3 weeks or longer. Auditory toxicity was reported in only three infants in the four studies that have evaluated once daily gentamicin compared with standard interval dose regimen [339]. Vestibular toxicity is difficult to assess in neonates and has not been evaluated. The precise mechanism involved in ototoxicity is unknown. Some evidence suggests that point mutations in mitochondrial DNA are relevant to explain hearing loss in selected persons following aminoglycoside treatment [298]. Even for the rare hospitalized infant with ototoxicity after receiving concurrent dosages of aminoglycosides, it is difficult to establish a direct causal relationship in many of the published studies because of their complicated clinical histories.

In recent years, the introduction of brainstem response audiometry has facilitated assessment of hearing during the neonate's hospital stay [363]. A blinded study of auditory brainstem responses in neonates who received amikacin or netilmicin showed a high incidence of transient abnormalities, but permanent bilateral sensorineural hearing loss occurred in 2% of infants in each of the amikacin, netilmicin, and control group [364]. In another study, significant delayed auditory brainstem responses were detected in 14 control infants and 15 neonates who received a daily dose of 5 to 7.5 mg/kg for 6 to 10 days of either gentamicin or tobramycin [365]. Long-term follow-up of these infants was not performed to document whether the abnormalities were transient or permanent. Other investigators failed to demonstrate permanent vestibular damage in 37 children aged 2 to 4 years who received netilmicin during the neonatal period [366].

Aminoglycoside-associated neuromuscular blockade has been reported only rarely [367–369]. The underlying mechanism appears to be inhibition of acetylcholine release at the neuromuscular junction by these drugs [370]. The aminoglycoside may act alone or synergistically with other neuromuscular blocking agents. Hypermagnesemia in newborns, often due to antenatal exposure to maternal magnesium administered for preeclampsia, may potentiate the neuromuscular blocking effects of aminoglycosides. Diagnosis is made by nerve conduction studies, which reveal a progressive fatigue and posttetanic facilitation characteristic of a nondepolarizing, curare-like neuromuscular block. Reversal of this block is achieved by neostigmine or calcium or both. Potentiation of neuromuscular blockade can be observed in infant botulism when aminoglycosides are administered to treat suspected sepsis [371]. Prophylactic treatment with calcium is not indicated because this cation may interfere with the antimicrobial activity of aminoglycosides against certain organisms. Newborns who require early surgical intervention and have large fluctuations in fluid volume and renal function are likely at the highest risk for this rare adverse event.

### PK-PD and Clinical Implications for Dosing *(Table 37–8; see Tables 37–7, 37–11)*

Aminoglycosides still remain effective for the initial empirical therapy in newborns with suspected gram-negative sepsis. The choice of the aminoglycoside to be routinely used is mainly dependent on the patterns of microbial resistance within a nursery. Amikacin remains one option for empirical treatment when multiply-resistant coliforms are frequently isolated within an individual neonatal unit. The aminoglycosides are usually safe to use in the newborn when administered according to the recommended dosage and with careful monitoring, particularly in premature infants of very low birth weight or infants with hypoxemia, renal dysfunction, or anesthetic effects. Therapeutic drug monitoring is needed to guide dosing in infants on ECMO.

Systemic aminoglycoside therapy remains an acceptable initial empirical treatment choice when meningitis is present because in combination with ampicillin, this agent offers potential synergistic activity against group B streptococci and *L. monocytogenes*. Aminoglycosides have been demonstrated to be effective for therapy for meningitis caused by susceptible gram-negative bacteria. However, if gram-negative bacilli are seen on CSF smears or later isolated as the causative agent of meningitis, third-generation cephalosporins or carbapenems should be considered. Combined therapy with a cephalosporins and an aminoglycoside is often used for the first 7 to 10 days of therapy for possible synergistic bacterial killing, and to prevent emergence of bacterial resistance during the treatment, especially for meningitis caused by *Serratia*, *Pseudomonas*, *Acinetobacter*, *Citrobacter*, and *Enterobacter* species.

Aminoglycosides demonstrate concentration-dependent bactericidal activity (see Table 37–7) [37]. In vitro time-kill curves and animal studies both demonstrate the increased rate and extent of killing with increasing concentration of aminoglycosides [372]. Early studies in gram-negative infections showed clinical response was associated with peak serum concentrations of greater than 7 µg/mL for gentamicin and tobramycin and 28 µg/mL for amikacin [373,374]. Subsequently, adult studies demonstrated effective response to therapy near 90% for a ratio of more than 8:1 for *E. coli* bacteremia [375] or 10:1 for gram-negative pneumonia [376]. The PD of aminoglycosides in the treatment of gram-negative infections has not been evaluated in infants.

In addition to therapeutic killing, high concentrations of aminoglycosides also provide a postantibiotic effect (PAE) (i.e., the sustained suppression of bacterial growth even after the antibiotic concentration is below the MIC of the target organism) [231]. In vitro, aminoglycosides demonstrate a PAE of 1 to 3 hours against *P. aeruginosa*

and 1 to 2 hours against Enterobacteriaceae [377]. Animal models suggest an even longer period of PAE, 2 to 7.5 hours [377,378]. The PAE is prolonged by increasing aminoglycoside concentration and in the presence of neutrophils [379]. PAE has not been demonstrated in clinical trials given ethical restraints of such studies. The duration of PAE is unknown in neonates but given the immature immunity of neonates, it may be less than calculated in animal models.

Ideally, dosing regimens for aminoglycosides would attempt to maximize killing, take advantage of the PAE, minimize adaptive resistance, reduce emergence of resistance, and diminish the potential for toxicity. Therapeutic drug monitoring is used to individualize dosage regimens. Peak serum concentrations should be maintained at 8 to 12 μg/mL for gentamicin and tobramycin, and at 20 to 30 μg/mL for amikacin to achieve the PD target (i.e., a peak (Cmax)/MIC ratio of >8 to 10). To potentially minimize the rare risk of toxicity, trough values are typically kept less than 2 μg/mL for the former drugs and less than 5 μg/mL for amikacin. To determine peak serum concentrations, blood samples are obtained 30 minutes after completion of the intravenous infusion or 45 to 60 minutes after an intramuscular administration. Trough serum concentrations are measured just before the next dose of the aminoglycoside.

In traditional or "standard" neonatal dosing regimens, gentamicin is administered at a dose of 2.5 mg/kg typically every 12 hours, with extended dosing intervals (18 to 24 hours) in preterm infants. The amikacin dosage is a 7.5 mg/kg dose to be used for infants weighing less than 2000 g and a 10 mg/kg dose for all other infants. For amikacin, a 12-hour dosing interval is recommended in the first week of life and an 8-hour interval used thereafter. Therapeutic drug monitoring is often used to individualize dosage schedules for infants weighing less than 1500 g at birth or born at less than 30 weeks of gestation.

### Use of Extended Dosing Intervals to Achieve PD Exposure Targets (Tables 37–8, 37–11)

The rationale for use of extended dosing intervals is based on several PK, pharmacodynamic, and microbiologic principles of aminoglycosides [263–265,339]: (1) Aminoglycosides exhibit concentration-dependent bacterial killing in which higher peak/MIC ratios are associated with improved bactericidal response; $C_{max}$/MIC ratios greater than 10 have been linked to superior efficacy of aminoglycosides against gram-negative bacteria, including *Pseudomonas*. (2) Aminoglycosides exhibit a postantibiotic effect (PAE) in which bacterial growth is suppressed despite serum concentrations below the MIC; drug concentrations, therefore, can remain below the pathogen's MIC for a period without compromising efficacy. (3) Nephrotoxicity is associated with aminoglycoside uptake into renal cells and possibly into the cochlea and vestibular membrane, but cellular uptake is more efficient with low

sustained concentrations and (in animals) uptake is a saturable process so that transient high peak levels do not lead to excessive drug accumulation. (4) Gram-negative bacteria have been shown to exhibit adaptive resistance after continuous exposure to aminoglycosides, a property that may be minimized by providing high bacteriocidal exposures minimizing time for bacterial growth in presence of antibiotic. (5) The lower glomerular filtration rate in neonates, especially the first few days of life and in preterm infants, suggest that more time for clearance may be needed to prevent toxic accumulation of aminoglycosides, and (6) once daily dosing is associated with less hospital cost. Although increased peak concentrations lengthen the duration of PAE, no research has been conducted in neonates to define the pharmacodynamics of this phenomenon in this age group.

Considerable evidence generated in adults with extended dosing intervals of aminoglycoside administration prompted studies in the pediatric and neonatal populations. Several comparison trials have been conducted in neonates to evaluate peak and trough gentamicin or amikacin concentrations after administration of "standard dosing" and "once-daily dosing" regimens (see Table 37–8) [296,380–384]. Mean peak concentrations in each study were higher in the once-daily regimen (5.9 to 10.7 μg/mL) than in the twice-daily group (3.9 to 7.4 μg/mL); and mean trough concentrations were lower in the daily group (0.8 to 1.9 μg/mL) than in the standard (1.0 to 2.8 μg/mL). Dose adjustment was indicated more often in the standard dosing groups. One study compared 2.5 to 3 mg/kg dosing every 24 hours and 4.5 to 5 mg/kg dosing every 48 hours in 58 very low birth weight infants (600 to 1500 g) [381]. The 48-hour dosing schedule achieved therapeutic serum concentrations and higher peak/MIC ratios for infecting microorganisms. Nearly one third of these infants, however, had extremely low serum gentamicin concentrations before the next dose, suggesting that a 36-hour interval might be more appropriate for very low birth weight infants. Another study evaluated single doses of 5 mg/kg of tobramycin and gentamicin administered at extended intervals and found that only 1.3% of these infants had subtherapeutic concentrations, compared with 26.8% of those given the traditional 2.5 mg/kg doses [382].

Once daily interval dosing was also explored for amikacin (see Table 37–8) [383–385]. In term infants, 15 mg/kg daily amikacin therapy in the first 3 days of life leads to significantly increased peak levels. Both regimens yield trough levels less than 5 μg/mL. Langhendries and colleagues then extended their study to include preterm infants, which received 15.5 to 20 mg/kg at a dosage interval of 24 to 42 hours depending on gestational age group. Dosage interval was also extended by 6 hours for infants with a history of hypoxia or who were receiving concurrent indomethacin therapy. In these preterm infants receiving extended interval amikacin dosing, the mean peak level was 27.8 μg/mL and mean trough level was 3.7 μg/mL. Amikacin-associated nephrotoxicity was not observed and results of BAERs evaluation were similar in study participants and nonstudy controls. No ototoxicity was reported in either study.

More recently, the Cochrane Collaboration performed a review of "standard multiple-doses a day" and "once-daily" dosing regimens of gentamicin for the treatment of suspected or proven sepsis in neonates in 11 trials and a total of 574 neonates [339]. All 36 infants with proven sepsis, regardless of treatment regimen, showed adequate clearance of sepsis. Once-daily dosing of gentamicin was superior in its ability to achieve a peak level of at least 5 μg/mL and a trough level less than 2 μg/mL. Ototoxicity and nephrotoxicity were not noted with either treatment regimen. They conclude that based on PK properties and PD targets, the once a day regimen may be superior in treating sepsis in neonates more than 32 weeks gestation. Based on these data and on proposed dosing guidelines to date, therapeutic recommendations for once daily or extended interval aminoglycosides are presented in Table 37–11.

## Aztreonam

Aztreonam is the first synthetic monocyclic β-lactam (monobactam) antibiotic approved for use in clinical medicine. Its aminoglycoside-like activity, good CSF penetration, and absence of nephrotoxic or ototoxic side effects make aztreonam potentially useful when combined with ampicillin for initial empirical therapy in newborns with severe, suspected sepsis.

### *Antimicrobial Activity*

Aztreonam has good activity against a broad spectrum of aerobic gram-negative bacteria, but its activity against gram-positive or anaerobic organisms is poor [1,386,387]. *Most E. coli*, *Klebsiella pneumoniae*, and *Citrobacter* species are inhibited by less than 1 μg/mL of aztreonam. *Serratia* and *Enterobacter* are less susceptible ($MIC_{90}$ of 1 to 4 μg/mL), whereas *H. influenzae* and *N. gonorrhoeae* are more susceptible ($MIC_{90}$ of 0.2 μg/mL or less). Higher concentrations of aztreonam are needed to inhibit growth of *P. aeruginosa* (MIC 8 to 12 μg/mL) [386,388]. Like other β-lactams, aztreonam exerts its antimicrobial activity by interfering with bacterial cell wall synthesis by binding to PBPs, especially PBP-3 of aerobic gram-negative bacteria. This drug is stable to hydrolysis by chromosome- or plasmid-mediated β-lactamases of the *Enterobacteriaceae* and does not induce chromosomal β-lactamase production.

### *Pharmacokinetic Data*

PK of intravenous aztreonam (20 to 30 mg/kg per dose of body weight) has been evaluated in a limited number of neonates [389]. Several small studies evaluated the pharmacokinetics following a 20 mg/kg per dose in neonates [390–396]. Serum concentrations and half-life decreased with chronologic age. The mean serum aztreonam concentration was 54 μg/mL in the first week of life and 45 μg/mL in infants 2 to 22 days of age. The half-life decreased from 3.5 to 6.6 hours in up to 3-day-old neonates, to 2.0 to 4.0 hours thereafter. Small premature infants weighing less than 1500 g have longer half-lives compared with larger preterm infants, 5.3 versus 4.1 hours, respectively [397]. A larger 30-mg/kg intravenous dose of aztreonam administered to infants weighing less than 2000 g during their first week of life resulted in peak serum concentrations from 65 to 79 μg/mL after the first dose and 77 to 83 μg/mL after 3 to 6 days of therapy [388]. Trough values were highly variable and ranged between

8.2 and 70.7 μg/mL. The half-life decreased from 7.6 to 5.5 hours after 3 to 6 doses. Older infants and young children have a shorter mean half-life of 1.7 hours [398].

Aztreonam has good penetration into the CSF of newborns with bacterial meningitis [399]. In a 7-day-old infant with newly diagnosed bacterial meningitis, a CSF concentration of 13.3 μg/mL was obtained 1.3 hours after an aztreonam dose, representing 18.8% of a simultaneously measured serum concentration. Pediatric patients with acute bacterial meningitis have concentrations of aztreonam in CSF that are 17% to 33% of serum values [400].

### Safety

Aztreonam appears to be well tolerated with no apparent side effects when given intravenously to newborns in PK studies. Adverse reactions described in adults include rashes, nausea, diarrhea, and eosinophilia, but their incidence is low [1,386,387]. Aztreonam effects on bowel flora are limited to a reduction in coliforms without significant changes in anaerobic bacteria. Colonization by resistant bacteria resulting from aztreonam therapy does not appear to be as much of a problem as that encountered with the use of the third-generation cephalosporins. Because aztreonam contains 780 mg of arginine per gram of antibiotic, concern has been raised regarding possible arginine-induced hypoglycemia [401]. Arginine is rapidly metabolized and can be transformed to glucose leading to transient hyperglycemia. As a result of this transient hyperglycemia, insulin concentrations can immediately rise, with the subsequent induction of hypoglycemia. These fluctuations in blood glucose and subsequent variation in insulin concentration can be potentially important in premature infants exposed to a metabolic stress. A study addressing this safety issue indicated that aztreonam was well tolerated and safe in premature infants when a glucose solution was concomitantly infused (at a glucose infusion rate greater than 5 mg/kg per minute) [402].

### PK-PD and Clinical Implications for Dosing

Aztreonam is still considered an investigational drug for neonates and infants younger than 3 months of age. Data from a prospective, randomized study of 58 neonates with infections caused by gram-negative bacilli, including *P. aeruginosa*, suggest that the use of aztreonam in combination with ampicillin is as effective as treatment with ampicillin and amikacin [401]. Individual aztreonam doses of 30 mg/kg given two to four times daily can achieve median peak serum bactericidal titers of about 1:16 and can maintain trough serum concentrations that exceed the $MIC_{90}$ for most gram-negative bacteria.

## CEPHALOSPORINS

Cephalosporins are semisynthetic derivatives of a 7-aminocephalosporanic acid nucleus [403,404]. The individual derivatives differ chemically by the addition of various side chains. The cephalosporins exert their antibacterial action in a manner similar to that described earlier for penicillin.

It has become customary to group cephalosporins into generations of agents on the basis of their antibacterial spectrum of activity. First-generation cephalosporins include cefazolin, cephalothin, cephalexin, and cefadroxil. Second-generation agents include cefaclor, cefprozil, cefamandole, cefuroxime, and loracarbef; and third-generation agents include cefoperazone, cefotaxime, ceftizoxime, ceftriaxone, and ceftazidime. A fourth-generation, cephalosporin and cefepime, has recently undergone PK evaluation in neonates. Cefepime has been shown to be effective for therapy for meningitis in children and should be useful for treatment of multiresistant gram-negative bacillary infections in pediatric patients. In the following section, we have focused on the most well-studied cephalosporins in neonates.

### Antimicrobial Activity

The *first-generation* cephalosporins such as cefazolin have good activity against gram-positive organisms but limited activity against gram-negative bacteria. Susceptible pathogens include streptococci, penicillin-susceptible and penicillin-resistant staphylococci, and penicillin-susceptible pneumococci. Although typically the activity against coliforms is good, other antibiotics are often preferred for treatment of infections caused by these organisms. *P. aeruginosa*, *Serratia marcescens*, *Enterococci*, MRSA, *L. monocytogenes*, *Enterobacter* species, indole-positive *Proteus* species, and *B. fragilis* all are resistant to these antibacterial agents [404].

Compared to first-generation cephalosporins, *second generation* agents have improved stability to hydrolysis by β-lactamases and therefore have increased activity against many gram-negative bacteria. Cefuroxime is more active than cephalothin against group B streptococci, pneumococci, and gram-negative enteric bacilli and also is active against *H. influenzae*, meningococci, gonococci, and staphylococci [405]. The second-generation agents have very poor activity against *P. aeruginosa*, enterococci, and *L. monocytogenes*.

The *third-generation* cephalosporins, such as cefotaxime and ceftazidime, have excellent in vitro activity against *H. influenzae*, gonococci, meningococci, and many gram-negative enteric bacilli. Ceftazidime and cefoperazone, however, are the only ones with adequate anti-*Pseudomonas* activity. *L. monocytogenes* and enterococci are uniformly resistant to these agents. Susceptibility of gram-positive organisms to these agents is variable but generally is lower than that to either first- or second- generation cephalosporins.

The *fourth-generation* cephalosporins demonstrate activity against gram-positive and gram-negative bacterial pathogens, including *P. aeruginosa*. Evidence also indicates that isolates of ceftazidime- and cefotaxime-resistant *Enterobacter* species are susceptible to cefepime [406]. Resistant organisms include enterococci, *L. monocytogenes*, MRSA, MRSE, and anaerobes.

Resistance to the cephalosporins develops through several mechanisms. Cephalothin and cefazolin can be inactivated by β-lactamases [407]. Exposure of some gram-negative bacteria, such as *P. aeruginosa* or *E. cloacae*, to second- or third-generation agents can induce the production of chromosomally mediated potent β-lactamases by these bacteria, which can hydrolyze even the β-lactamase-stable cephalosporins [407]. Several plasmid-mediated β-lactamases have been shown to play a role in the resistance of certain gram-negative enteric bacilli to third-generation cephalosporins [408]. Other mechanisms of resistance

include alterations in the permeability of the outer membranes of gram-negative bacteria to these drugs that limit their ability to reach the PBP target sites. Mutations leading to functional or quantitative changes in PBPs constitute an additional means by which bacteria can resist the antimicrobial action of these drugs [407,408].

## Pharmacokinetic Data

### Cefazolin

The intramuscular administration of 25 mg/kg doses of cefazolin (Table 37–9) produces serum concentrations of 55 to 65 μg/mL, respectively, 1 hour after the dose. The concentrations at 12 hours drop to 13 to 18 μg/mL, respectively [409]. Intravenous doses of 25 mg/kg administered to six premature infants 2 to 12 days of age resulted in mean serum concentrations of 92, 79, 48, and 12 μg/mL at 0.5, 1, 4, and 12 hours, respectively, after the end of the infusion [410]. The drug is excreted in the urine in unchanged form [411]. The serum half-life of cefazolin decreases from 4.5 to 5 hours in the first week of life to approximately 3 hours by 3 to 4 weeks of age. CSF penetration of cefazolin is poor.

### Cefuroxime

The intramuscular administration of 10 mg/kg doses of cefuroxime (see Table 37–9) produces serum concentrations that range between 15 and 25 μg/mL 30 to 60 minutes after the injection [412]. Intramuscular doses of 25 mg/kg given to neonates weighing less than 2.5 kg during their first week of life produce mean serum concentrations of 49, 30, and 15 μg/mL at 2, 4, and 8 hours after the injection, respectively [413]. For larger newborns, the corresponding values were lower (34, 21, and 9 μg/mL, respectively). In a study of preterm and term infants receiving cefuroxime 25 mg/kg every 12 hours, median steady state serum concentrations were 45, 26, and 11 μg/mL after 0.5, 5 and 12 hours respectively [414]. Repeated administration of the drug did not result in serum accumulation. About 70% of the daily cefuroxime dose could be recovered in urine in a 24-hour period. Half-life times have been reported to range from 2 to 11 hours (mean, 6 hours). CSF cefuroxime concentrations of 2.3 to 5.3 μg/mL were measured in three newborns with meningitis [412]. These values represented 12% to 25% of the corresponding serum concentrations. In three other neonates without meningeal inflammation, concentrations were lower and ranged from 0.4 to 1.5 μg/mL.

### Cefotaxime

About 80% of the cefotaxime (see Table 37–9) dose is excreted in urine; however, only a third of the drug is eliminated in unchanged form [415]. Cefotaxime is rapidly metabolized in the body to desacetyl-cefotaxime through the action of esterases found in the liver, erythrocytes, and other tissues [415]. This metabolite is biologically active, but its antibacterial activity is generally lower than that of cefotaxime. Synergistic interactions against many organisms can be demonstrated when these two compounds are combined in vitro [416]. Desacetyl-cefotaxime accounts for 15% to 45% of the peak and 45% to 70% of the trough concentrations of total cefotaxime [417–419].

Several investigators have evaluated the PK properties of cefotaxime in newborns [417–422]. About 80% of the cefotaxime dose is excreted in urine; however, only a third of the drug is eliminated in unchanged form [415]. A 25 mg/kg intravenous dose produces concentrations of 60 to 80 μg/mL immediately after the end of drug infusion, which decreases to 35 to 50 μg/mL 30 minutes later [419,421]. Serum cefotaxime concentrations are higher in premature newborns and in those younger than 1 week of age. The administration of a 50 mg/kg intravenous dose during the first week of life results in peak serum concentrations of 116 μg/mL (range, 46 to 186 μg/mL) in low birth weight infants, compared with 133 μg/mL (range, 76 to 208 μg/mL) in term neonates [417]. Values decline thereafter to approximately 34 to 38 μg/mL 6 hours after the dose. The mean half-life is 4.6 hours for low birth weight neonates and 3.4 hours for larger newborns [417].

Both cefotaxime and its metabolite penetrate well into the CSF of infants with meningitis [421,423,424]. Concentrations of 7.1 to 30 μg/mL are detected 1 to 2 hours after a 50 mg/kg intravenous dose and represented 27% to 63%, respectively, of simultaneously measured serum values. CSF concentrations as high as 20 μg/mL in neonates with or without meningitis have been reported [423].

### Ceftazidime

Numerous reports on the PK of ceftazidime (see Table 37–9) in neonates have been published [13,422,425–434]. Peak serum concentrations of 35 to 269 μg/mL (mean, 77 μg/mL) have been observed after intravenous administration of 25- to 30-mg/kg doses of ceftazidime to newborns of various gestational ages during their first week of life [432,434]. Mean trough values measured 9 to 12 hours after the dose are from 15 to 19 μg/mL [426,429–432]. These concentrations are higher than those detected in older infants receiving identical ceftazidime dosages. When the dose is increased to 50 mg/kg intravenously, mean peak serum concentrations are 102 to 118 μg/mL and mean trough values 8 hours after the dose are from 29 to 41 μg/mL [13,428]. Most of the ceftazidime dose is excreted in the urine. Not surprisingly, the mean elimination half-life is inversely related to gestational age and varies from 4.2 to 6.7 hours. The peak serum concentrations 1 to 2 hours after the intramuscular administration of 50 mg/kg of ceftazidime are about 67% lower than those observed with intravenous infusion [13,429]. Neonatal exposure to indomethacin or to asphyxia decreases the glomerular filtration rate and clearance of ceftazidime.

Ceftazidime penetrates well into the CSF, especially when meningitis is present [431,435]. In infants with bacterial meningitis, CSF concentrations of 1.8 to 7.9 μg/mL are obtained 2 to 7 hours after a 50-mg/kg dose, corresponding to 6% to 46% of a simultaneous serum concentration [436]. The extent of penetration is lower in patients with aseptic meningitis and relatively poor in those with uninflamed meninges [431,437].

### Cefepime (Table 37–9)

Recent PK studies in neonates given a 50 mg/kg intravenous dose every 12 hours have shown a mean $C_{max}$ of 89 [438] and 121 [439] μg/mL, half-life of 4.9 [438] and 4.3 [439] hour, and clearance of 1.2 mL/min/kg [438,439].

**TABLE 37–9** Pharmacology of Cephalosporins

| Drug Dose | Route of Elimination | Infant Characteristics | $C_{max}$ (μg/mL) | Half-life (hr) | PK:PD Target | Protein Binding | CSF* Penetration with Meningitis | CLSI MIC* *E. coli Klebsiella* | CLSI MIC* *P. aeruginosa* | Clinical Pearls‡ |

**From references 32, 683.*

*†Metabolites maintain antimicrobial activity but less than cefotaxime.*

*‡Safety considerations for cephalosporins: Hypersensitivity, diarrhea, eosinophilia, BM suppression, risk factor for candidiasis in extremely preterm infants, seizures related to massive exposure.*

Penetration into CSF appears to be good, with CSF concentrations averaging 3.3 to 5.7 μg/mL at 0.5 and 8 hours after drug administration [440].

### Safety

In general, cephalosporins are well tolerated by neonates. Adverse reactions that have been observed, mostly in older patients, include hypersensitivity reactions, diarrhea, thrombophlebitis, pain on intramuscular injection, eosinophilia, leukopenia, granulocytopenia, and seizures related to the administration of massive doses of these drugs [441,442]. Falsely elevated serum creatinine concentrations have been observed in patients who received cefoxitin or cephalothin. Alterations of the bowel bacterial flora are most pronounced with the third-generation agents, especially ceftriaxone and cefoperazone, and can lead to intestinal colonization by resistant organisms such as *Candida*, *Pseudomonas*, *Enterobacter*, or *Enterococcus* species. Subsequent superinfections by these drug-resistant pathogens have been described in neonates [441,443]. Another potential adverse effect related to disruption of bacterial intestinal flora by potent cephalosporins is the induction of antibiotic-associated colitis, presumably caused by overgrowth of toxin-producing *C. difficile*.

Bleeding disorders occurring with the use of cephalosporins have been well documented, mostly in adults. Hemostatic abnormalities associated with the use of cephalosporins can be mediated by several mechanisms. Immune-mediated platelet destruction with resultant thrombocytopenia is very rare but has been associated with the administration of cephalothin, cefazolin, cefamandole, cefaclor, and cefoxitin in older patients [444]. A second rare mechanism involves the development of antibodies, usually immunoglobulin G (IgG), against certain clotting factors such as factor V or VIII. Platelet dysfunction can be observed after several days of therapy with any of the cephalosporins. These drugs may inhibit adenosine diphosphate (ADP)-induced platelet aggregation, with resultant prolongation of the bleeding time. The effect is slowly reversible after discontinuation of the drug [445]. Another mechanism is defective fibrinogen-to-fibrin conversion, which has been observed with drugs such as cefazolin and cefamandole, particularly in patients with renal failure, who have very high serum antibiotic concentrations [444,445].

The most important mechanism is hemostatic abnormalities involving interference with the production of vitamin K-dependent clotting factors (II, VII, IX, and X), with resultant hypoprothrombinemia [445]. This effect-observed most commonly with moxalactam and cefamandole therapy and rarely with cefotaxime and ceftriaxone therapy—is believed to be related to, but not necessarily caused by, the presence of the N-methylthiotetrazole side chain in moxalactam, cefamandole, and cefoperazone. In patients with inadequate dietary intake, inhibition of colonic bacteria such as *E. coli* or *Bacteroides*, which are capable of vitamin K production, may lead to hypoprothrombinemia secondary to vitamin K deficiency. This side effect usually is avoidable or reversible by the administration of supplemental vitamin K.

An immune-mediated severe hemolytic reaction to ceftriaxone has been described in children and adults. Because ceftriaxone has a high avidity for protein binding, a theoretical concern is that its use in the neonatal period can be associated with a significant displacement of bilirubin from albumin-binding sites, thereby inducing a hyperbilirubinemia. Ceftriaxone, when given to neonates in the first days of life, has been associated with an immediate and prolonged decrease in the reserve albumin concentration, which could predispose a vulnerable infant to bilirubin encephalopathy.

### Clinical Implications

Cephalosporins, like other β-lactams, have time dependent bacterial killing properties [29,30,36]. Therefore, the pharmacodynamic target associated with bacterial killing is time>MIC. For most of these drugs, clearance occurs through renal elimination. As neonatal kidneys mature, dosing intervals need to decrease to provide therapeutic drug concentrations above the MIC of target organisms.

The usefulness of first-generation cephalosporins for therapy for neonatal bacterial infections is restricted. Their activity against gram-negative bacteria is limited and unpredictable, and their penetration into the CSF is relatively poor; thus, these drugs are not indicated for initial therapy for suspected neonatal bacterial infections. Cefazolin dosing is typically 25 mg/kg given intravenously every 12 hours for newborns weighing less than 2000 g in the first 2 weeks of life and every 8 hours for older infants. Extremely preterm infants may continue twice a day dosing for up to 28 days of life. For infants weighing more than 2000 g, the dose is given every 8 to 12 hours in the first week of life and every 8 hours thereafter. Use in neonates is generally limited to prophylaxis of perioperative infections, and treatment of urinary tract and soft tissue infections caused by susceptible organisms.

Although second-generation cephalosporins have been successfully used to treat neonatal infections caused by susceptible bacteria, these antibiotics are not typically recommended for routine use because of limited experience in newborns and because of their inferior activity to that of third-generation agents against gram-negative bacteria. With the advent of multidrug-resistant pneumococci, other antibiotics, such as amoxicillin-clavulanate, are preferred for treatment of neonatal otitis media.

As a group, third-generation cephalosporins are useful agents for the treatment of suspected or proven bacterial infections in newborns. Their advantages include excellent in vitro activity against the major pathogens for newborns, including aminoglycoside-resistant gram-negative bacilli, adequate CSF penetration with resultant high bactericidal activity in CSF of infants with meningitis, and a proven record of safety and tolerability [446]. Indications for use of individual agents vary in accordance with their pharmacologic properties.

The clinical efficacy and safety of cefotaxime in the treatment of neonatal infections have been well documented in several studies [421,443,447,448]. Cefotaxime is typically not used alone for initial therapy in suspected sepsis because of its poor activity against *L. monocytogenes* and enterococci. The addition of ampicillin provides antibacterial coverage against these organisms. One potential problem associated with the routine use of this drug is the

possible emergence of cefotaxime-resistant gram-negative bacteria in the nursery [443]. Some nurseries, however, have not documented this problem even after 2 years of continuous use of this antibiotic [447]. Cefotaxime reaches CSF concentrations that are 50 to several hundred times greater than the $MIC_{90}$ of susceptible gram-negative enteric bacilli or group B streptococci isolated from newborns with meningitis, and has therefore been shown to be effective for the treatment of neonatal meningitis caused by susceptible bacteria [449]. The dosage of cefotaxime in newborns is 50 mg/kg every 12 hours during the first week of life and every 8 hours thereafter. In full-term infants older than 3 weeks, a 6-hour regimen can be used for treatment of meningitis [450].

I do not recommend using ceftazidime alone for initial therapy for suspected neonatal sepsis because this antibiotic is not active against enterococci and *L. monocytogenes* and because of the possibility for emergence of cephalosporin-resistant gram-negative organisms. Several treatment failures have occurred when the offending organism proved to be a gram-positive bacterium [431]. Increased colonization and superinfection by resistant organisms such as enterococci and *C. albicans* have been encountered in patients receiving ceftazidime [433,451]. The use of ceftazidime is typically reserved for situations in which gram-negative bacteria, notably *P. aeruginosa*, have been isolated or are strongly suspected of being the causative microorganisms in neonates with sepsis, meningitis, or other invasive infections. The dosage is 100 mg/kg/day in two (in infants born weighing less than 2000 g) or three (in those born at 2000 g or greater) divided doses during the first week of life and 150 mg/kg/day in three divided doses for older neonates.

Cefepime has been evaluated in young children with serious bacterial infections, including meningitis, and has been comparable in safety and efficacy to third-generation cephalosporins [452]. Recent PK information supports the typical dosing regimen, 30 mg/kg every 12 hours during first two weeks of life and 50 mg/kg every 12 hours thereafter. Meningitis or severe infections due to *Pseudomonas* or *Enterobacter* species may require dosing every 8 hours to maintain the concentrations above the MIC of the offending organism. Although data on the use of cefepime in the neonatal period are lacking because of its extended activity and stability against β-lactamase-producing bacteria, cefepime can be used for treatment of multidrug-resistant gram-negative infections. In a small randomized trial of 90 infants, cefepime was safe and therapeutically equivalent to cefotaxime for treatment of bacterial meningitis in infants and children [453].

## BROAD-ACTING AGENTS WITH ACTIVITY AGAINST PSEUDAMONAS (See Table 37–9)

### β-Lactam/β-lactamase Inhibitor Antibiotics

#### *Antimicrobial Activity*

Combination β-lactam and β-lactamase inhibitor antibiotics (piperacillin/tazobactam, ticarcillin/clavulanate) offer broad spectrum activity and have re-emerged as an alternative to extended spectrum cephalosporins and the emergence of cephalosporin-induced pathogen resistance [454]. These drugs are bactericidal against many organisms with the exception of methicillin resistant staphylococcus and enterococcus (ticarcillin/clavulanate). Recently, the use of ß-lactam/ß-lactamase combination antibiotics have become appealing in neonates because of their safety profiles and their decreased likelihood to propagate bacterial resistance compared with extended-spectrum cephalosporins. However, more PK and PD knowledge in neonates is needed to optimize dosing guidelines. These agents are not typically recommended for treatment of central nervous system infections because penetration of β-lactamase inhibitors has not been well defined.

### Piperacillin-Tazobactam

#### *Antimicrobial Activity*

Piperacillin is formulated with the β-lactamase inhibitor tazobactam in an 8:1 ratio for intravenous preparation [455]. Piperacillin is an acylampicillin, a semisynthetic penicillin that is a piperazine derivative of ampicillin. Piperacillin is active against a broad range of gram-positive and gram-negative bacteria including *S. aureus*, streptococci, *H. influenzae*, *N. meningitidis*, *L. monocytogenes*, *K. pneumoniae*, *P. mirabilis*, *S. marcescens*, and many anaerobes. In contrast to ticarcillin, piperacillin has better activity against enterococci and *P. aeruginosa*. In vitro synergistic activity with gentamicin has been demonstrated against *P. aeruginosa*, coliforms, and susceptible *S. aureus* strains. Synergy and antagonism has been demonstrated with cephalosporins perhaps due to the ability of some cephalosporins to induce β-lactamase production [456–458]. Because piperacillin is susceptible to hydrolysis by β-lactamase, it is now manufactured with a β-lactamase inhibitor, tazobactam. Piperacillin-tazobactam is not approved by the FDA for use in infants less than 2 months of age. However, it has been considered for neonates with proven bacterial infections, particularly those infected with difficult to treat polymicrobial sepsis or infections due to *P. aeruginosa* or *K. pneumoniae*.

#### *Pharmacokinetic Data (Table 37–9)*

Piperacillin and tazobactam are widely distributed into tissue and body fluids, including the intestinal mucosa and biliary system; however, distribution into cerebrospinal fluid is low in adults with noninflamed meninges as with most penicillins [1,454,455,459–461]. Protein binding is estimated to be 30% for both piperacillin and tazobactam. Each drug is eliminated primarily through the kidneys via glomerular filtration and tubular secretion with approximately 70% excreted as unchanged, active drug in the urine in children and adults. The primary nonrenal route of elimination is biliary excretion [460,462]. Piperacillin metabolite desethyl piperacillin maintains some microbiologic activity, whereas the single metabolite of tazobactam does not.

Piperacillin/tazobactam is approved for use in children and infants older than 2 months [463–465]. Elimination is dependent on renal function and therefore improves with age until adult clearance is achieved around 2 years of age. Children receiving piperacillin/tazobactam have somewhat

reduced piperacillin elimination and prolonged half-life (0.7 hour vs. 0.5 hour) compared with piperacillin alone likely because of competitive antagonism for renal tubular secretion [465,466].

The PK of piperacillin has been evaluated in 98 neonates (29 to 40 weeks of gestation) in the first 2 weeks of life [467,468]; however, the PK of piperacillin/tazobactam has not been described. Preterm neonates have lower peak piperacillin concentrations due to their higher volume of distribution. In the first week after birth, the mean peak serum concentration after an intravenous 75 mg/kg dose is 180 μg/mL, 233 μg/mL, and 207 μg/mL for infants 29 to 31 weeks, 33 to 35 weeks, or 38 to 40 weeks of gestation. Immature renal function leads to prolonged half-life and delayed clearance, thus allowing preterm infants to maintain concentrations over the dosing interval. The mean 12-hour trough concentrations ranged from 20 μg/mL in 29- to 31-week gestational infants to 5 μg/mL in term infants [468]. In the second week of life, 8-hour trough concentrations ranged from 19 μg/mL for less than 33-week-gestation infants to 6 μg/mL for term infants [468]. Piperacillin half-life similarly decreases with advanced gestational age, chronologic age, and birth weight consistent with renal maturation. The prolonged half-life in neonates decreases from 6 hours in the first 2 days after birth, to 4 hours in the first week, and to 2 hours by the second week [467,468]. Infants with septic shock and significant renal insufficiency have prolonged half-life up to 14 hours. In older infants, the reported half-life of piperacillin is 0.75 hours in 1- to 6-month-old infants [464] and for piperacillin/tazobactam is 1.4 hours for 2- to 6-month-old infants [463].

CSF piperacillin concentrations of 2.6 to 6 μg/mL were measured in three neonates without meningitis within 7 hours of the intravenous administration of a 100-mg/kg dose [467]. In one infant with *Pseudomonas* meningitis, piperacillin reached a concentration of 19 μg/mL in the CSF 2.5 hours after administration of a 200 mg/kg intravenous dose [467]. Human and animal models suggest that modest CSF penetration is expected for β-lactamase inhibitors [469].

### Safety

In a prospective, randomized, comparative, open-label trial of children with severe intra-abdominal infections, patients receiving piperacillin/tazobactam had a similar rate of adverse reactions when compared with those receiving cefotaxime and metronizdazole [1,470,471]. Adverse events reported in more than 1% of children in this study including diarrhea, fever, vomiting, local reaction, abscess, sepsis, abdominal pain, infection, bloody diarrhea, pharyngitis, constipation, and elevated SGOT enzyme. These adverse events were infrequent compared with transient complications encountered in adult trials. Bleeding manifestations, neuromuscular excitability, and seizures have occurred in patients receiving β-lactam antibiotics, including piperacillin. Impaired hemostasis secondary to platelet dysfunction occurs less frequently than with carbenicillin and ticarcillin [445]. The sodium content in piperacillin is less than half that in ticarcillin, which may be important in some newborns with cardiac or renal disease.

### PK-PD and Clinical Implications for Dosing

Piperacillin-tazobactam, either alone or combined with aminoglycosides, has been used successfully for the treatment of bacteriologically proven neonatal infections [454]. Neonatal PK knowledge and clinical experience is limited and dosing recommendations remain empirical. Piperacillin and tazobactam are both mainly eliminated through the kidney by glomerular filtration and tubular secretion. Therefore it is rational to have initial dosage regimens for piperacillin-tazobactam based upon the PK of piperacillin; however, PK studies of piperacillin-tazobactam are still needed.

The PD of efficacy for β-lactam antibiotics depends on the time that the drug concentration exceeds the MIC for the pathogen. To maintain piperacillin concentrations above the MIC, the dosing interval may need to be shortened for susceptible pathogens with MICs greater than 4 to 8 μg/mL, such as can be seen for *Pseudomonas*, *Enterobacter*, or *Klebsiella* [463]. Given the modest CSF penetration, higher dosages may be considered for meningitis.

Dosing recommendations are variable and hindered by the paucity of PK data. One study suggested that piperacillin doses of 100 mg/kg every 12 hours may be appropriate and that a dose of 200 mg/kg every 12 hours should be used for meningitis [467]. In another PK study [468], a dosage schedule of 75 mg/kg given every 12 hours during the first week after birth and every 8 hours thereafter for infants less than 36-week gestation was recommended. For full-term infants, a 75-mg/kg dose given every 8 hours during the first week after birth and every 6 hours thereafter was recommended. Neonatal trough concentrations at 8 to 12 hours would help ensure that levels can be maintained above the MIC for at least 60% of the dosing interval.

## Ticarcillin-Clavulanate (See Table 37–9)

Ticarcillin is a semisynthetic penicillin with pharmacologic and toxic properties virtually identical to those of other semisynthetic penicillin [472,473]. The coadministration of clavulanic acid with ticarcillin significantly enhances the antibacterial activity of the latter drug against several organisms, including some ticarcillin-resistant strains of *E. coli*, *K. pneumoniae*, *P. mirabilis*, and staphylococci [474,475]. *Enterococcus* species are resistant to ticarcillin. Clavulanate is a β-lactam with weak antibacterial activity, but it has the property of being a potent irreversible inhibitor of several ß-lactamases produced by gram-positive and gram-negative bacteria. Current ticarcillin-clavulanate combination formulation (Timentin R) is approved for children greater than 3 months of age for the treatment of bacterial sepsis, respiratory infections, urinary tract infections, and intra-abdominal infections [1]. Information regarding the use of this compound in newborns is limited. Ticarcillin activity against *P. aeruginosa* and its formulation with the ß-lactamase inhibitor clavulanate make it attractive for serious bacterial disease of neonates [476]. Synergy with aminoglycosides has been demonstrated for the treatment of some strains of *Pseudomonas*.

### Pharmacokinetic Data

Ticarcillin-clavulanate is available for intravenous administration in a 30:1 ticarcillin-clavulanate ratio [1,472,473]. Like piperacillin, ticarcillin is eliminated via glomerular

filtration and renal tubular secretion. Approximately 60% to 70% of ticarcillin is excreted unchanged in urine during the first 6 hours after administration. However, only 30% to 40% of clavulanic acid is excreted unchanged in the urine while the remainder undergoes nonrenal metabolism. Ticarcillin is approximately 45% protein bound whereas clavulanic acid is approximately 25% protein bound. Ticarcillin penetrates well into bile and pleural fluid.

PK data for ticarcillin-clavulanic acid has been assessed in 64 preterm and term neonates; however, the ratio of ticarcillin/clavulanate was not consistent between reports [477–480]. In a study of 24 newborns (25 to 39 weeks of gestation) who received 80 mg/kg ticarcillin and 3.5 mg/kg clavulanate, the ticarcillin peak serum concentrations (mean 183 μg/mL, range 100 to 400) and half-life (mean 4.5 hours, range 1.2 to 9.5) are similar to those observed after administration of ticarcillin alone [480]. The ticarcillin and clavulanate half-lives were shorter in term infants (ticarcillin 2.7 hours, clavulanate 1.4 hours) than in preterm infants (ticarcillin 4.2 hours, clavulanate 2.6 hours) [479]. Similar results were reported for the one PK study that evaluated the commercially available product with a 30:1 ratio of ticarcillin:clavulanate [478].

Ticarcillin and clavulanate have different PK profiles. Ticarcillin is renally eliminated and clearance improves with renal maturation and chronologic age. Alternatively, clavulanate is eliminated through nonrenal mechanisms and is more rapid [454]. Ticarcillin accumulates in young neonates due to renal immaturity; however, clavulanate does not and therefore the ticarcillin:clavulanate ratio observed in older patient is not likely maintained in neonates. Simulation of ticarcillin and clavulanate exposure using a population PK model [478] suggested that a lower dose (50 mg/kg ticarcillin) administered more frequently (i.e., every 6 hours) was needed to maintain both ticarcillin and clavulanate levels. The significance of altered ticarcillin:clavulanate ratios is unclear [481] since we do not know the optimal duration or concentration for serum clavulanate.

### *Safety*

Ticarcillin-clavulanate possesses the characteristic safety profile of other penicillin antibiotics. Adverse reactions include anaphylaxis, bleeding disorders, seizures, headache, gastrointestinal disturbances, transient elevation hepatic enzymes, hypernatremia, and hypokalemia. Ticarcillin-clavulanate has been studied in 296 children (>3 months old) in controlled trials and another 408 children in uncontrolled clinical trials [1]. Clinical trials in neonates are lacking. Anecdotal reports and small case-series suggest that ticarcillin-clavulanate is well tolerated in neonates.

### *PK-PD and Clinical Implications for Dosing (Table 37–10)*

Ticarcillin-clavulanate is typically used along with an aminoglycoside for infants with severe gram-negative enteric infections or *Pseudomonas* sepsis, anecdotally with satisfactory safety and effectiveness. The most consistent dosing recommendation for neonates is 50 mg/kg every 6 hours, the same dose as recommended in infants greater than 3 months of age with moderate infections. Frequent dosing is needed to maintain clavulanic acid levels since clavulanic acid clearance is more rapid than ticarcillin in infants. Clavulanic acid CSF penetration is only modest and is inconsistent in adult and animal models; therefore its use in treatment of CNS infections is discouraged. Ticarcillin-clavulanate should not be mixed in the same container or administered simultaneously with an aminoglycoside because of the physical and chemical incompatibilities between these two drug classes.

## Carbapenems

Carbapenems (see Table 37–9) are β-lactam antibiotics known for their exceptionally broad activity and activity against extended spectrum ß-lactamase-producing gram-negative organisms [1,482]. *Imipenem* was the first drug in this new class. However, imipenem is susceptible to degradation by the enzyme dehydropeptidase-1 in the kidney and therefore imipenem is now formulated with cilastatin, a dehydropeptidase inhibitor. The coadministration of both imipenem/cilastatin (1:1 ratio) increases the urinary concentration of imipenem, prolongs the imipenem serum half-life, and appears to prevent the nephrotoxicity induced by high doses of imipenem. Cilastatin itself has no intrinsic antimicrobial activity. *Meropenem* is a newer carbapenem that is not susceptible to dehydropeptidase degradation. Meropenem is structurally different from imipenem in two ways: the carbapenem ring structure of meropenem includes an additional ß-methyl group in the C-1 position, providing stability against the human renal tubular enzyme dehydropeptidase and a long, substituted pyrrolidine side chain present in the C-2 position allows greater activity against intracellular target sites in organisms such as *P. aeruginosa* [483]. Meropenem was approved by the FDA for use in children older than 3 months on the basis of extensive pediatric investigations across a wide range of infections, including meningitis and complicated abdominal infections [484]. Meropenem is being increasingly studied in neonates for the treatment of complicated intra-abdominal infections\infections due to *Pseudomonas* or extended spectrum ß-lactamase producing bacterial infections. The newest carbepenems, ertapenem and doripenem, have yet to be studied in infants.

### *Antimicrobial Activity*

Imipenem and meropenem have an exceptionally broad spectrum of activity. The bacterial species considered resistant to these drugs are MRSA, methicillin-resistant *S. epidermidis*, *Stenotrophomonas maltophilia*, *Burkholderia cepacia*, and *E. faecium* [482]. These drugs maintain activity against extended spectrum ß-lactamase (ESBL) producing organisms. It has been estimated that approximately 98% of unselected bacterial pathogens isolated from humans are susceptible to carbapenems at concentrations of 8 μg/mL or less [485,486]. Carbepenems produce in vitro $MIC_{90}$ values of 1 μg/mL against the most commonly isolated species of gram-positive and enteric gram-negative aerobic bacteria including group B streptococci, penicillin-susceptible and penicillin-resistant *S. pneumoniae*, MSSA, *L. monocytogenes*, *Citrobacter freundii*, *E. coli*, *H. influenzae*, *Klebsiella*, *Proteus*, *Serratia, and Acinetobacter* species. The $MIC_{90}$ values are typically less than 2 μg/mL for anaerobic bacteria [482,485]. *P. aeruginosa* has an $MIC_{50}$ and $MIC_{90}$ of 1 and greater than

8 for imipenem/cilastatin and of 0.5 and 16 for meropenem, respectively. Meropenem is consistently more active against *P. aeruginosa* than imipenem. These inhibitory concentrations against *P. aeruginosa* are comparable to those of ceftazidime. Synergistic interactions between carbapenems and aminoglycosides can be demonstrated in vitro against *P. aeruginosa* and *S. aureus* isolates. Antagonistic interactions usually are observed when imipenem is combined with other ß-lactams, probably as a result of chromosomal ß-lactamase induction by imipenem [485].

Carbapenem's unusually broad antibacterial spectrum is related to its ability to penetrate efficiently the outer membrane of gram-negative bacteria, its high binding affinity for PBP-2, and its resistance to hydrolysis by both plasmid- and chromosomally mediated ß-lactamases [486,487]. Some ß-lactamases produced by *S. maltophilia*, *Aeromonas hydrophila*, and *B. fragilis*, however, are capable of hydrolyzing imipenem and meropenem. Emergence of carbapenem-resistant strains during therapy with this drug is rare except in the case of *P. aeruginosa*, in which resistance occurs in as many as 17% of isolates [482].

## Pharmacokinetic Data

### Imipenem-Cilastatin

For both imipenem and cilastatin (Table 37–10), serum concentration is directly proportional to the administered dose [483,488,489]. Higher serum concentrations are achieved with cilastatin than with identical doses of imipenem. Imipenem when co-administered with cilastatin is eliminated as active drug through the kidneys [485]. Cilastatin is excreted primarily in unchanged form in the urine, but about 12% of the drug appears as the metabolite N-acetylcilastatin [485].

In neonatal studies, the intravenous administration of 10-, 15-, 20- and 25-mg/kg doses of both drugs results in mean peak imipenem concentrations of 11, 21, 30, and 55 μg/mL, respectively, compared with mean cilastatin values of 28, 37, 57, and 69 μg/mL, respectively [488,489]. After 3 to 4 days of treatment with 20-mg/kg intravenous doses of imipenem-cilastatin every 12 hours, peak serum concentrations are 35 and 86 μg/mL for imipenem and cilastatin, respectively. The mean serum half-life of imipenem is about 2 hours, whereas that of cilastatin is 5 to 6.4 hours [488]. The half-life for both drugs is inversely related to birth weight and gestational age and is considerably longer than the 1-hour half-life reported for both drugs in older infants and in healthy adult volunteers [488–491]. During the neonatal period, the plasma clearance of cilastatin is only about 25% of that of imipenem [488].

Although both imipenem and cilastatin penetrate well into the CSF in the presence of meningeal inflammation [492,493], data derived from neonatal studies are scant. In one newborn who received a 15-mg/kg intravenous dose, concentrations of 1.1 and 0.8 μg/mL were noted for imipenem and cilastatin, respectively, at 1.5 hours after injection. In a second neonate who received a 25-mg/kg dose, CSF values of 5.6 and 1.8 μg/mL were found for imipenem and cilastatin, respectively [489].

### Meropenem

Meropenem (Table 37–10) was approved by the FDA for use in children older than 3 months of age on the basis of extensive pediatric investigations across a wide range of infections, including meningitis and complicated abdominal infections [1,494]. Small PK studies have been published in infants born at 23 to 40 weeks of gestation and up to 60 days of age [483,495,496]. Meropenem exhibits dose-proportional linear PK properties with dosages of meropenem from 10 to 40 mg/kg. A 20 mg/kg dose of meropenem results in peak serum concentrations of about 50 μg/mL. Meropenem clearance increases with gestational age and chronologic age as the kidneys mature. In the most recent population PK study of meropenem in preterm and term infants, serum creatinine and postmenstrual age were the best overall predictor of meropenem clearance [495]. Half-life, volume of distribution, and total drug clearance of meropenem were 3 hours, 0.46 to 0.74 L/kg, and 1.8 to 2.6 mL/min/kg, respectively, for premature infants and 2 hours, 0.48 L/kg, and 3.15 mL/min/kg for full-term neonates. The half-life decreases to 1.6 hours at 2 to 5 months of age as renal maturation occurs.

## Safety

Both imipenem-cilastatin and meropenem appear to be well tolerated when administered intravenously to newborns in relatively small PK studies. In a review of studies conducted worldwide including thousands of patients, most of whom were adults, it was observed that the nature and frequency of side effects were similar to those of other ß-lactam antibiotics; these adverse effects consisted mainly of nausea, vomiting, diarrhea, thrombophlebitis, thrombocytosis, eosinophilia, and elevation of hepatic enzyme concentrations [497]. Colonization by *Candida* or imipenem-resistant bacteria occurred in about 16% of patients, and secondary superinfection was noted in about 6% [497]. Alterations of bowel flora in children given imipenem-cilastatin have been minimal in the few patients studied in detail [493]. A worrisome report suggests that imipenem treatment in infants with bacterial meningitis was possibly associated with drug-related seizure activity [498]. In infants with bacterial meningitis, seizures developed in 7 of 21 infants (33%), aged 3 to 48 months following imipenem therapy. In this study [498], CSF imipenem and cilastatin peak concentrations ranged from 1.4 to 10 μg/mL and 0.8 to 7.2 μg/mL, respectively. It is believed that interference of ß-lactam antibiotics with the inhibitory effects of the neurotransmitter gamma-aminobutyric acid (GABA) can result in epileptiform bursts [499,500]. In mice, imipenem has been shown to induce seizure activity at serum concentrations two to three times lower than those of penicillin and cefotaxime [501]. Meropenem has less affinity than imipenem for the gamma-aminobutyric acid receptor and consequently has demonstrated a lower propensity to cause seizures in animal models [502]. In infants and children with meningitis, treatment with meropenem was well tolerated, and no drug-related seizure activity was observed [494].

## PK-PD and Clinical Implications for Dosing (*Table 37–10*)

Imipenem-cilastatin and meropenem are not recommended for routine use in the treatment of suspected or proven neonatal infections with rare exceptions. Both agents should be primarily reserved to treat infections caused by multidrug-resistant microorganisms. Data in

**Based upon anecdotal clinical experience, neonatal and hospital formularies and notable references [153,690,691,692].*
*Dosing for infants <1200 g is typically based upon limited PK information. Use of most of these drugs remain off-label in neonates due to need for more pharmacokinetic and safety information. Higher dosing may be indicated for treatment of meningitis or micro-organism with higher MIC, such as* Pseudomonas. *In the absence of complete pharmacokinetic information across gestation age and postnatal ages, interhospital variability in dosing guidance is expected.*
†*Adjustments of further dosing intervals should be based on aminoglycoside half-lives calculated after serum peak and trough concentrations measurements.*
IM, *intramuscular;* IV, *intravenous;* ODD, *once-daily dosing;* PO, *oral;* SDD, *standard daily dosing.*

25 neonates with proven bacterial infections suggest that single-drug therapy with imipenem-cilastatin using a 25-mg/kg dose given two to four times daily is both efficacious and safe [503]. Because newborns have lower renal clearance capability and somewhat greater blood-brain permeability than those in older infants and children, high concentrations of imipenem-cilastatin could be achieved in the CSF of neonates, especially those with bacterial meningitis, potentially resulting in drug-related seizure activity. Evidence from case reports suggests that meropenem also is safe and effective for treatment of neonatal infections. Because meropenem is more active against *P. aeruginosa*, not metabolized in the kidney, and has not been linked to the potential induction of seizures, we believe that if a carbapenem is selected for therapy in a newborn, meropenem should be the agent of choice.

Meropenem, like other β-lactam antibiotics, exhibits time-dependent killing, so the goal of therapy is to keep meropenem serum concentrations above the MIC for at least 40% of the dosing interval for immunocompetent patients [30]. Some authors have recommended higher T>MIC intervals in immunocompromised patients and particularly those with *Pseudomonas* infections due to the higher $MIC_{50}$ of 4 and $MIC_{90}$ of 32. The meropenem dose exposure relationship has been evaluated using Monte Carlo simulation and the population PK model. In the first 2 weeks after birth, 20 mg/kg of meropenem administered every 8 hours can maintain the PK-PD target of 60% T>MIC in more than 99% of preterm and term infants if the pathogen is susceptible with a MIC value of less than 8 μg/mL [495]. NICU-specific sensitivities for nosocomial pathogens must be considered when considering appropriate exposure. Higher dosing will need to be determined for meningitis and for the treatment of the more resistant organisms such as *P. aeruginosa*. Further studies are required before these drugs can be recommended for use in select newborns and before an appropriate dosage schedule can be formulated.

## ANTIVIRAL MEDICATIONS

Viral infections in the neonate are fortunately rare yet associated with significant morbidity and mortality. Viral therapy is available for the treatment of HIV, HSV, CMV, and VZV. The pharmacology of medications used to treat or prevent HIV infections is discussed in Chapter 21 and has been recently reviewed [504–506]. The pharmacology of acyclovir, ganciclovir, and oseltamivir will be reviewed here [1]. These drugs need further PK investigation in neonates.

### Acyclovir for the Treatment of HSV

Acyclovir is a nucleoside analogue used against herpes simplex virus (HSV) and varicella-zoster virus. The PK of acyclovir in neonates requires further investigation. PK is limited to 3 infants (less than 60 days old) receiving oral acyclovir (300 mg/m$^2$) for 3 doses [507]. The maximum concentration (1.88 μg/mL) was higher than observed in adults receiving a larger dose (400 mg/m$^2$) and suggests adequate bioavailability. The elimination half-life of 3 hours was longer than the 2.4 hours observed in adults. Mortality was reduced in infants with neonatal HSV disease who received high dose, 60 mg/kg/day, compared with infants receiving 45 mg/kg/day (given every 8 hours) for 21 days [508,509]. The survival rate was similar for infants with CNS disease. Neutropenia was the most significant adverse event reported; however, there were no reported adverse sequelae and the neutropenia was transient. The dosing interval may need to be increased in premature infants who are expected to have decreased creatinine clearance [510].

### Ganciclovir for the Treatment of Congenital CMV

#### *Antimicrobial Activity*

Ganciclovir is approved for the prevention or treatment of cytomegalovirus virus in adults [1].

Ganciclovir is a synthetic guanine derivative that specifically inhibits viral DNA synthesis by inhibiting viral DNA polymerase resulting in termination of viral DNA elongation [511,512]. Ganciclovir is active against CMV and, to a lesser extent, HSV.

#### *Pharmacokinetic Data*

Ganciclovir is phosphorylated by viral protein kinases to ganciclovir triphosphate, the active metabolite that persists for days in CMV-infected cells [512]. To a lesser degree, normal, uninfected cells can generate monophosphorylated ganciclovir, thus possibly explaining its cytotoxic side effects [513]. Ganciclovir exhibits low protein binding. CSF penetration is 24% to 70% of the respective plasma concentrations. Renal excretion of unchanged drug occurs by glomerular filtration and active tubular secretion. Half-life in adults is 3.5 hours. Dose adjustment is advised in renal insufficiency. Ganciclovir exhibits linear kinetics with dose escalation.

Single dose, intravenous ganciclovir PK has been evaluated in 27 neonates less than 50 days old. After a 4 mg/kg or 6 mg/kg intravenous dose, the peak concentration was 5.5 and 7.0 μg/mL, respectively; systemic clearance was 3.14 and 3.56 mL/kg/min, respectively; and the half-life was 2.4 hours for both doses [514]. Clearance was less than the 4.7 mL/kg/min reported in children but the half-life was similar; neonates had high interpatient variability. Population PK analysis of these newborns showed that ganciclovir clearance was associated with body weight and creatinine clearance [515]. The mean population clearance was 0.4 L/hr and the volume of distribution was 1.73 L. A recent population PK analysis in young infants receiving intravenous ganciclovir or oral valganciclovir showed similar results, namely a mean clearance of 0.32 L/hr and volume of distribution of 1.78 L [516]. Because ganciclovir is eliminated through the kidney, we would expect a delay in drug clearance during the first week of life and in extremely premature infants.

*Valganciclovir* is the oral prodrug of ganciclovir. Valganciclovir is rapidly hydrolyzed to ganciclovir. PK studies of valganciclovir are limited [516–520]. A recent study of 24 neonates reported that 16 mg/kg oral valganciclovir administered twice daily achieves similar exposure to the 6 mg/kg per dose intravenous ganciclovir regimen and the target $AUC_{0-12}$ of 27 mg*hr/L [520]. The median bioavailability was 41%. Ganciclovir clearance doubled over the 6 weeks of therapy and the AUC was reduced nearly 50%. However, infants receiving valganciclovir had more consistent AUC over 6 weeks of therapy, likely because bioavailability increased by 32% over the course of treatment. This dose was consistent with the 15 mg/kg dose recommended in smaller studies [519]. Viral load decreased in all infants (median 0.7 log viral DNA copies per milliliter); however, this decrease in viral load was not associated with $C_{max}$ or AUC. Neutropenia remained the most significant adverse effect and grade 3 to 4 neutropenia occurred in 38% of infants, and was correlated with higher $C_{max}$ and higher AUC.

#### *Safety*

Ganciclovir label contains a black box warning for risk of granulocytopenia, anemia, and thrombocytopenia, and the drug should be avoided in patients with cytopenia or history of cytopenia. Dose reduction is also indicated in renal impairment. Additional reported adverse events include fever, anorexia, and vomiting. Ganciclovir has important drug interactions: it should not be combined with imipenem-cilastin due to concern for seizures and caution is required when combined with other nucleoside analogues, cyclosporine, and amphotericin B due to potential additive toxicity.

In a placebo-controlled trial of ganciclovir in infants, neutropenia occurred in 63% of infants receiving ganciclovir compared with 21% in the control infants [521]. Adverse events in infants participating in a phase 2 study of 8 versus 12 mg/kg/day included retinal detachment, neutropenia, and a moderate increase in creatinine and liver enzymes [522]. It remains unclear if these adverse events were attributed to either progression of CMV disease, adverse drug effect, or both. Periodic monitoring of blood counts, serum creatinine, and liver function is recommended, and hematologic manifestations are typically transient.

### PK-PD and Clinical Indications

Ganciclovir is indicated for the treatment of CMV retinitis in immunocompromised patients or the prevention of CMV disease in transplant recipients. The relationship between ganciclovir exposure and clinical response has not been established. In vitro studies have shown that median inhibitory concentrations ranged from 0.02 to 3.48 μg/mL. A placebo-controlled trial in neonates with central nervous system manifestations, demonstrated a reduction of hearing deterioration in infants receiving intravenous ganciclovir 12 mg/kg/day for 6 weeks [521]. Safety and efficacy of ganciclovir has not been established for congenital CMV disease. There was a higher incidence of neutropenia in infants receiving ganciclovir compared with placebo. Controversy exists regarding the potential benefits of prolonged ganciclovir therapy to neonates given the prolonged duration of intravenous access required and risk of adverse drug events [523]. Oral valganciclovir, a prodrug that is rapidly hydrolyzed to ganciclovir and approved for use in adults, is under investigation in children and neonates.

## Oseltamivir for the Treatment of Influenza

The CDC estimates that each year more than 200,000 hospitalizations and 36,000 deaths are attributable to influenza in the United States [524,525]. In the 2003–2004 influenza seasons, the CDC reported 153 influenza-related deaths in children with a median age of 3 years. The highest mortality rate in children was among children younger than 6 months of age. In addition to mortality, children are known to have high rates of hospitalization and can suffer chronic neurologic or neuromuscular conditions [526–530]. Neonates and young infants are particularly vulnerable because vaccination is ineffective and antiviral treatment is not recommended in infancy. Immunization of pregnant mothers and all adults who contact infants is the best means of preventing influenza infection in infants. Neuraminidase inhibitors are effective in the treatment of sensitive influenza species in infants older than 1 year of age if initiated within 48 hours of symptoms.

### Antimicrobial Activity

Neuraminidase inhibitors inhibit influenza virus type A and type B by binding to a highly conserved region of the neuraminidase protein on the viral surface to inhibit viral penetration, replication, and disease [531]. The only neuraminidase inhibitor available for oral treatment in children younger than 6 years is oseltamivir [1,532] because this drug has been shown to be safe and effective at reducing both the duration and severity of influenza symptoms in adult and pediatric patients over the age of 1 year [533–538]. However, neuraminidase inhibitor resistance among circulating influenza strains is increasing.

### Pharmacokinetic Data

Oseltamivir PK has been established in adults and children more than 1 year of age [532,539], but infant PK is unknown. Oseltamivir has excellent bioavailability after oral dosing and is extensively converted by hepatic esterases to oseltamivir carboxylate. At least 75% of an oral dose reaches the systemic circulation as the active form oseltamivir carboxylate. This active form is then renally excreted. Oseltamivir carboxylate is not a substrate for, nor an inhibitor of, cytochrome P450 enzymes. PK analysis in children revealed that younger patients cleared both the prodrug and the active metabolite faster than adult patients, resulting in a lower exposure for a given milligram per kilogram dose.

### Safety

Oseltamivir has been well tolerated in adult and pediatric clinical trials [1,535,536,540,541]. The most common reported adverse events are related to gastrointestinal disturbances, particularly nausea and vomiting, but its safety has not been determined in infants under 1 year of age. Roche Laboratory, Inc. issued an alert in 2003 that oseltamivir should not be used in infants younger than 1 year old because one animal study showed high mortality in 7-day-old rats treated with 500 times the typical human dose [542]. Interestingly, rats treated with 250 times the typical human dose did not experience side effects or mortality. These young rats had higher plasma levels of prodrug and higher drug concentrations in the CNS than older rats; however, levels far exceeded those experienced in human studies. The relevance to humans remains unknown and there is great uncertainty in extrapolating juvenile animal data to human infants. The Better Pharmaceutics for Children Act (BPCA) executive summary states that it was considered unlikely that infants older than 3 to 6 months of age would be at significant risk [543]. Two case series of oseltamivir treatment in a total of 154 infants under 1 year of age revealed no serious complications [544,545].

In response to the H1N1 epidemic, the FDA in October 2009 issued an Emergency Use Authorization for Oseltamivir to include dosing recommendations for infants less than 1 year of age. In light of the limited data on safety and dosing, health care providers are encouraged to limit use to infants with confirmed H1N1 influenza or infant that have been exposed to a confirmed 2009 H1N1 influenza case and to carefully monitor for adverse events [546].

### Clinical Implication

Infants are at high risk for influenza associated morbidity and mortality. In infants hospitalized with influenza, the possible benefit of therapy may outweigh the risks. An ongoing clinical trial supported by the NICHD funded Collaborative Antiviral Study Group will provide safety and PK information for oseltamivir in neonates and young infants.

## ANTIFUNGAL MEDICATIONS

In the extremely premature infant, invasive candidiasis is common, often fatal, and frequently results in severe neurodevelopmental impairment. The therapeutic agents of choice in the nursery have been fluconazole and amphotericin products. Echinocandins are emerging as first-line therapy in older patients and their PK, safety, and efficacy are under investigation in young infants.

A hallmark of neonatal candidiasis is (CNS) infection. The incidence of CNS involvement is higher in the young infant than older patients; and invasive candidiasis (isolation of *Candida* from normally sterile body fluids) from any source has been associated with neurodevelopmental

impairment. The diagnosis of CNS disease is very difficult, such that CNS involvement should be presumed in the young, premature infant.

## Meningoencephalitis

CNS infection is not limited to meningitis; CNS infection with *Candida* is more accurately described as meningoencephalitis. Because the infection is based in brain tissue, it is likely that brain tissue penetration is more important to management of CNS infection with *Candida* rather than a strict assessment of penetration into the cerebrospinal fluid. This helps explain why amphotericin B deoxycholate and the echinocandins are likely to be effective in treating invasive candidiasis in young infants, provided that the levels of these products in the blood are sufficiently high to drive the product into the brain.

## Amphotericin B

Amphotericin B (approved in 1958) is so named because it is amphoteric, forming soluble salts in both acidic and basic environments [547]. However, because of its insolubility in water, amphotericin B for clinical use is actually amphotericin B mixed with the detergent deoxycholate in a 3:7 mixture [547,548].

### Antimicrobial Activity

Amphotericin products bind to ergosterol, the major sterol found in fungal cytoplasmic membranes [549,550]. The lipophilic amphotericin B acts by preferential binding to fungal membrane ergosterols, creating transmembrane channels, which result in an increased permeability to monovalent cations. The fungicidal activity is believed to be due to a damaged barrier and subsequent cell death through leakage of essential nutrients from the fungal cell. Amphotericin B also has oxidant activity, which disrupts cellular metabolism, inhibits proton ATPase pumps, depletes cellular energy reserves, and promotes lipid peroxidation to result in an increase in membrane fragility and ionized calcium leakage [549,550].

### Pharmacokinetic Data

Amphotericin B is released from its carrier and is distributed very efficiently (greater than 90%) with lipoproteins. The antifungal drug is taken up preferentially by organs of the reticuloendothelial system, and follows a three-compartment distribution model. There is an initial 24- to 48-hour half-life reflecting uptake by host lipids, very slow release, and excretion into urine and bile, and a subsequent terminal half-life of up to 15 days [551]. In a small series ($n = 13$) evaluating the pharmacokinetics of amphotericin B among premature infants ($27.4 \pm 5$ weeks), nine subjects showed elimination of amphotericin B at steady state with an estimated elimination half-life of 14.8 hours. The rest of the infants, however, showed minimal drug elimination during the dosing interval suggesting substantial drug accumulation and interindividual variability [552]. In a small series of premature infants born at 27.4 ($\pm$ 5) weeks gestational age ($n = 5$), CSF amphotericin B concentrations were 40% to 90% of serum concentrations obtained simultaneously [552].

### Safety

Tolerance to amphotericin B deoxycholate is limited by its acute and chronic toxicities. In addition to fungal ergosterol, the drug also interacts with cholesterol in human cell membranes; this likely accounts for its toxicity [553]. Amphotericin B also has a constrictive effect on renal arterioles, leading to a reduction in the glomerular filtration rate [554]. Up to 80% of older patients receiving amphotericin B develop either infusion-related toxicity or nephrotoxicity [547]; however, the product is likely better tolerated in young infants. Renal function usually returns to normal after cessation of amphotericin B, although permanent renal impairment is common after larger doses in older patients [555].

### PK-PD and Clinical Implications

Experimental in vitro and in vivo studies support concentration-dependent killing with a prolonged post-antifungal effect, suggesting large daily doses will be most effective and that achieving optimal peak concentrations is important [556]. Peak levels are achieved 1 hour after a 4-hour infusion and reach a plateau at the third consecutive day of a constant dose. (4). The total dose administered over time correlates with increased tissue concentrations, suggesting a progressive accumulation with continued drug administration [557]. However, there is no evidence of a clinical dose effect [558] to support higher doses (greater than 1 mg/kg/day) of amphotericin B [559]. Cerebrospinal fluid (CSF) values are only 2% to 4% of serum concentrations and sometimes difficult to detect [560]. Yet, a small case series completed in young infants suggests that the penetration of the product may be greater in this population. As the drug penetrates well into brain tissue, 1 mg/kg dosing should be sufficient for central nervous infections (see “Meningoencephalitis”).

## Amphotericin B Lipid-Associated Formulations

In addition to conventional amphotericin B deoxycholate, three fundamentally different lipid-associated formulations have been developed that offer the advantage of an increased daily dose of the parent drug, better delivery to the primary reticuloendothelial organs (lungs, liver, spleen), and reduced toxicity: amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD), and liposomal amphotericin B (L-amphotericin B) [561–563].

ABLC is a tightly packed, ribbon-like structure of a bilayered membrane formed by combining dimyristoylphosphatidylcholine, dimyristoyl phosphatidylglycerol, and amphotericin B in a ratio of 7:3:3. ABCD is composed of disklike structures of cholesteryl sulfate complexed with amphotericin B in an equimolar ratio. L-amphotericin B consists of small, uniformly sized unilamellar vesicles of a lipid bilayer of hydrogenated soy phosphatidylcholine-distcaryl phosphatidylglycerol-cholesterol-amphotericin B in the ratio 2:0.8:1:0.4 [564,565].

### Pharmacokinetic Data

Lipid formulations of amphotericin B generally have a slower onset of action and are less active than amphotericin B alone in time-kill studies, presumably due to the required disassociation of free amphotericin B from the lipid

vehicle [566]. It is postulated that activated monocytes/macrophages take up drug-laden lipid formulations and transport them to the site of infection, where phospholipases release the free drug [563]. The different PK and toxicities of the lipid formulations are reflected in the dosing recommendations: ABLC is recommended at 5 mg/kg/day, ABCD at 3 to 5 mg/kg/day, and L-amphotericin B at 1 to 5 mg/kg/day. However, most clinical data have been obtained with the use of these preparations at 5 mg/kg/day.

The dosage of 5 mg/kg/day is especially pertinent to the young infant given the frequency of CNS disease (see previous "Meningoencephalitis" section). Animal studies suggest that on a similar dosing schedule, the lipid products are almost always not as potent as amphotericin B, but that the ability to safely administer higher daily doses of the parent drug improves their efficacy [560], such that they compare favorably with the amphotericin B deoxycholate preparation with less toxicity. A multicenter maximum-tolerated-dose study of L-amphotericin B using doses from 7.5 to 15 mg/kg/day found a nonlinear plasma pharmacokinetic profile with a maximal concentration at 10 mg/kg/day and no demonstrable dose-limiting nephrotoxicity or infusion-related toxicity [567].

Lipid formulations have the added benefit of increased tissue concentration compared with conventional amphotericin B, specifically in the liver, lungs, and spleen. However, it is not entirely clear whether these higher concentrations in tissue are truly available to the microfoci of infection. L-amphotericin B has a comparatively higher peak plasma level and prolonged circulation in plasma [565], while ABCD has a lower plasma level than amphotericin B after infusion but a longer half-life and larger volume of distribution [568].

### Safety Data

Lipid formulations appear to stabilize amphotericin B in a self-associated state so that it is not available to interact with the cholesterol of human cellular membranes [565,569]. Another theory for the decreased nephrotoxicity of lipid formulations is the preferential binding of amphotericin B to serum high-density lipoproteins compared with amphotericin B's binding to low-density lipoproteins [570]. The high-density lipoprotein-bound amphotericin B appears to be released to the kidney more slowly, or to a lesser degree. For infusion-related toxicity there is a general agreement that L-amphotericin B has less toxicity than ABLC, whereas ABCD appears closer in toxicity to conventional amphotericin B [571,572].

Several reviews have focused on amphotericin B PK in children. In one study of five premature infants and five older children, the volume of distribution was smaller and the elimination clearance more rapid than previously reported in adults. Serum levels were approximately half of those in adults with comparable doses, and interpatient variability was marked in the premature infants [573].

### PK-PD and Clinical Implications for Dosing

Antifungal efficacy is dependent on the $AUC_{0-24}$. The key target organ is the brain, even if the lumbar puncture is normal. Killing of the organism in the brain depends not only on $AUC_{0-24}$ but also total AUC exposure during therapy. That is, CNS disease usually requires extended therapy [574]. So while many sources suggest 1 or 2 weeks of antifungal therapy, we suggest at least 21 days. We acknowledge that optimal length of therapy is not known as of this writing.

There are no data or consensus opinions among authorities indicating improved efficacy of any new amphotericin B lipid formulation over conventional amphotericin B [561,563,567,571,575]. This fact leaves the clearest indication for a lipid formulation over amphotericin B to be reducing nephrotoxicity; however, nephrotoxicity in the young infant is thought to be uncommon.

## Pyrimidine Analogues: 5-Fluorocytosine

5-Fluorocytosine (5-FC) is a fluorinated analogue of cytosine synthesized as a potential antitumor agent and initially approved for use in 1972 [561]. Unfortunately, most reports detail clinical failure with monotherapy for yeast infections [576]. The antimycotic activity of the drug results from the rapid conversion of 5-FC into 5-fluorouracil (5-FU) within susceptible fungal cells [577,578]. The two mechanisms of action of 5-FU are incorporation into fungal RNA in place of uridylic acid to inhibit fungal protein synthesis, and inhibition of thymidylate synthetase to inhibit fungal DNA synthesis [578]. The latter appears to be the dominant mechanism. Clinical and microbiologic antifungal resistance appears to develop quickly to 5-FC monotherapy.

### Pharmacokinetic Data

Fungistatic 5-FC is thought to enhance the antifungal activity of amphotericin B, especially in anatomic sites where amphotericin B penetration is often suboptimal, such as cerebrospinal fluid (CSF), heart valves, and the vitreal body [558]. 5-FC penetrates well into most body sites because it is small, highly water soluble, and not bound by serum proteins to any great extent [578]. In a study involving 33 neonates in the UK treated with intravenous or oral 5-FC that underwent therapeutic drug monitoring, drug concentrations were low (trough, <20 mg/L or peak, <50 mg/L) in 40.5%; undetectable in 5.1%; high (trough level >40 mg/L or peak >80 mg/L) in 38.9%; and potentially toxic (>100 mg/L) in 9.9% [579].

### Safety

The mechanism of toxicity for 5-FC is unknown; but toxicity is common and substantial. 5-FC may exacerbate myelosuppression; toxic levels may develop when in combination with amphotericin B due to nephrotoxicity of the amphotericin B and the decreased renal clearance of 5-FC [580]. If 5-FC is used, routine serum level monitoring is warranted because peak serum concentrations of 100 μg/mL or greater are associated with bone marrow aplasia. Approximately 50% of patients who receive the product experience substantial toxicity, including azotemia, renal tubular acidosis, and myelosuppression [581]. The product is also known to cause gastrointestinal complications and in the premature infant at risk for necrotizing enterocolitis, its use should be undertaken with extreme caution. Given the narrow therapeutic range and need for therapeutic drug monitoring and the need for oral administration in the United States, this drug is seldom used in neonates.

### Clinical Implications

Nearly all clinical studies involving 5-FC are combination antifungal protocols for cryptococcal meningitis due to the inherently rather weak antifungal activity of 5-FC monotherapy. The use of 5-FC in premature neonates is discouraged. A study evaluating risk factors and mortality rates of neonatal candidiasis among extremely premature infants showed that infants with *Candida* meningitis who received amphotericin B in combination with 5-FC experiences a prolonged time to sterilization of the CSF compared with those receiving amphotericin B monotherapy (median of 17.5 versus 6 days, respectively) [582].

## Azoles: Fluconazole and Voriconazole

The azoles are subdivided into imidazoles and triazoles on the basis of the number of nitrogens in the azole ring [549,583], with the structural differences resulting in different binding affinities for the cytochrome P-450 (CYP) enzyme system. The triazoles are the products used in young infants and will be covered here. Of the older first-generation triazoles, fluconazole is effective against most *Candida* species, but it is unreliable for the treatment of *Candida glabrata* and it is ineffective against the very rare cases of neonatal *Aspergillus* infections. Newer, second-generation triazoles (voriconazole, posaconazole, and ravuconazole) are modifications of prior triazoles with an expanded antifungal spectrum of activity and generally lower MIC values than the older compounds [584]. Only voriconazole has been investigated in children younger than 12 years.

### Antimicrobial Activity

The azole antifungals are heterocyclic synthetic compounds that inhibit the fungal cytochrome P-$450_{14DM}$ (also known as lanosterol 14a-demethylase), which catalyzes a late step in ergosterol biosynthesis [583]. The drugs bind to the heme group in the target protein and block demethylation of the C-14 of lanosterol, leading to substitution of methylated sterols in the membrane and depletion of ergosterol. The result is an accumulation of precursors with abnormalities in fungal membrane permeability, membrane-bound enzyme activity, and lack of coordination of chitin synthesis [585,586].

## Fluconazole

Fluconazole (Diflucan; Pfizer Inc., New York) is a bis-triazole approved by the FDA for use in treating cryptococcosis and *Candida* infections in 1990. An in vitro time-kill study showed that the rate of fluconazole fungistatic activity was not influenced by concentration once the maximal fungistatic concentration was surpassed, which is in contrast to the concentration-dependent fungicidal activity of amphotericin B [587] or caspofungin [588]. Fluconazole is well absorbed from the gastrointestinal tract and is cleared predominantly by the renal route as unchanged drug, whereas metabolism accounts for only a minor proportion of fluconazole clearance [589]. Binding to plasma proteins is low (12%) [590]. Gastric absorption of oral fluconazole is virtually unaffected by pH or the presence of food in the stomach.

Fluconazole is available as either an oral or an intravenous form, and oral fluconazole has a high bioavailability of approximately 90% relative to its intravenous administration. Fluconazole passes into tissues and fluids very rapidly, probably due to its relatively low lipophilicity and limited degree of binding to plasma proteins. Concentrations of fluconazole are 10- to 20-fold higher in the urine than in blood, and drug concentrations in the CSF and vitreous humor of the eye are approximately 80% of those found simultaneously in blood [590]. The concentrations of fluconazole in body fluids such as vaginal secretions, breast milk, saliva, and sputum are also similar to those in blood, and the fluid to blood ratio remains stable after multiple doses. There is a linear plasma concentration-dose relationship.

Simple conversion of the corresponding adult dosage of fluconazole on a weight basis is inappropriate for young infants. A recent population PK study in premature infants suggests that maintenance fluconazole doses of 12 mg/kg/day are necessary to achieve exposures similar to older children and adults [591]. In addition, a loading dose of 25 mg/kg would achieve steady state concentrations sooner than the traditional dosing scheme. This strategy is currently being evaluated in a phase I clinical trial.

### Safety

Side effects of fluconazole are uncommon. In one study of 24 immunocompromised children, elevated transaminases were observed in only two cases [592]. A large review of 78 reports that used fluconazole in a total of 726 children younger than the age of 1 year showed it was generally well tolerated [593]. Another review of 562 children from 12 clinical studies confirmed that pediatric results mirror the excellent safety profile seen in adults. The most common side effects were gastrointestinal upset (7.7%) (vomiting, diarrhea, nausea) and a skin rash (1.2%) [594]. Fluconazole affects the metabolism of cyclosporine, leading to its increased concentration when they are used together [595].

### PK-PD and Clinical Implications for Dosing

Fluconazole may be used as monotherapy for treatment of candidiasis in the nursery. It should be given 12 mg/kg daily. There does not appear to be antagonism if the product is used with amphotericin B. In a multicenter trial of 236 patients with invasive candidiasis, those treated with fluconazole plus amphotericin B versus fluconazole alone trended toward better success and more rapid resolution of *Candida* fungemia with the combination [596]. Fluconazole is particularly appropriate for urinary tract infections due to its concentrating effect in the bladder. Fluconazole is also effective for superficial skin infections because the stratum corneum:serum ratio is high [597].

Some centers use fluconazole for prophylaxis; however, this is not yet considered standard of care. In a single-center blind trial over a 30-month period 100 infants with birth weights less than 1000 g, those infants who received fluconazole for 6 weeks had a decrease in the development of invasive fungal infection compared with the placebo (0% vs. 20%) [598]. A larger prospective, randomized double-blind, controlled trial conducted in 8 NICUs in Italy among 322 infants with birth weight

less than 1500 g showed that a fluconazole prophylaxis regimen of 3 to 6 mg/kg several times per week for 4 to 6 weeks reduced the incidence of *Candida* colonization [9.8% in the 6 mg group, 7.7% in the 3 mg group, and 29.2% in the placebo group ($P$ <.001)] and invasive fungal infections [2.7% in the 6 mg group (P=0.005), 3.8% in the 3 mg group (P=0.02), and 13.2% in the placebo group] [599]. A retrospective study evaluating the incidence of invasive candidiasis and *Candida*-related mortality among infants with birth weights less than 1000 g who received fluconazole prophylaxis (3 mg/kg several times per week) for 6 weeks showed that the incidence of invasive candidiasis and *Candida*-associated mortality decreased. In the group receiving fluconazole, no increase in fluconazole resistant *Candida* strains was observed [600]. Similarly, another report demonstrated that the use of fluconazole prophylaxis for 4 to 6 weeks in infants with birth weights less than 1500 g did not increase the incidence of fungal colonization and infections caused by natively fluconazole-resistant *Candida* species [601].

Results of fluconazole prophylaxis studies in premature infants are encouraging; however, the universal implementation of such a strategy across nurseries has not been broadly used because: (1) the rate of *Candida* infections vary greatly among centers [602] and (2) there are insufficient neurodevelopmental follow-up data in these infants to justify prophylaxis [603]. A multicenter international trial is underway to answer questions regarding the need of prophylaxis based on rates of systemic *Candida* infections in individual nurseries.

## Voriconazole

Voriconazole (VFend; Pfizer Inc., New York) is a second-generation triazole and a synthetic derivative of fluconazole. Voriconazole has activity against most *Candida* species and against *Aspergillus* [604–608].

### Pharmacokinetic Data

Voriconazole is extensively metabolized by the liver and its bioavailability in adults is approximately 90%. It appears that CYP2C19 plays a major role in the metabolism of voriconazole, and this enzyme exhibits genetic polymorphism, dividing the population into poor and extensive metabolizers as a result of a point mutation in the gene encoding the protein CYP2C19 [609]. About 5% to 7% of the white population has a deficiency in expressing this enzyme, so genotype plays a key role in the pharmacokinetics of voriconazole [610]. As many as 20% of non-Indian Asians have low CYP2C19 activity and can achieve voriconazole levels as much as fourfold greater than those homozygous subjects who metabolize the drug more extensively [611].

Voriconazole is 44% to 67% plasma bound with nonlinear pharmacokinetics, has a variable half-life of approximately 6 hours [612] with large interpatient variation in blood levels [613] and good CSF penetration [584,585,614–618]. Time-kill studies against *Candida* species and *Cryptococcus neoformans* revealed in vitro non-concentration-dependent fungistatic activity, similar to that of fluconazole [587].

Oral absorption is nonlinear and rapid, with an approximately fivefold accumulation over 14 days in one study of hematologic malignancy patients [618]. In a study assessing voriconazole levels after intravenous-to-oral switching, mean voriconazole levels did fall following oral administration compared with intravenous administration, but most subjects achieved steady state 4 days after dosing began. Maximum plasma voriconazole levels occurred at the end of the 1-hour intravenous infusion and between 1.4 and 1.8 hours after oral administration [611]. A PK study in six cirrhosis patients demonstrated hepatic-impaired patients should receive the same oral loading dose, but half the maintenance dose [619]. In contrast to adults, elimination of voriconazole follows linear kinetics in children. They have a higher elimination capacity and therefore require a larger (4 mg/kg twice daily vs. 3 mg/kg twice daily) maintenance dose [124,125] after a 6-mg/kg load for two doses the first day of therapy [620,621]. The kinetics of the product in young infants are not known.

### Safety

Voriconazole's main side effects include reversible dose-dependent visual disturbances (increased brightness, blurred vision) [618,622] in as many as one third of treated patients, elevated hepatic transaminases with increasing doses [622], and occasional skin reactions likely due to photosensitization [585,605,623]. The visual side effects have resulted in great caution in the use of the product in premature infants because of the concern of the developing retina as a target organ for toxicity. No such long-term effects have been observed nor studied in the young infant; however, most clinicians reserve this product for the occasional case of aspergillosis [624] and as a third-line agent for candidiasis.

### PK-PD and Clinical Implications

A multicenter trial of voriconazole versus fluconazole for treating esophageal candidiasis in 391 immunocompromised patients showed similar success rates with voriconazole (98.3%) and fluconazole (95.1%) [625], although overall safety and tolerability of both antifungals were acceptable. In an open-label evaluation of 58 children with a proven or probable invasive fungal infection (most had aspergillosis). 45% percent of children had a complete or partial response, and only 7% were discontinued from voriconazole because of intolerance. The most commonly reported adverse events in these children included elevation in hepatic transaminases, skin rash, and photosensitivity reaction, and abnormal vision. Intravenously administered voriconazole has been used successfully in preterm infants of very low birth weight with primary cutaneous aspergillosis [626].

## Echinocandins

### Antimicrobial Activity

A relatively new class of antifungals, the echinocandins and the amino-containing pneumocandin analogues, are cyclic hexapeptide agents that interfere with cell wall biosynthesis by noncompetitive inhibition of 1,3-β-D-glucan synthase, an enzyme present in fungi but absent in mammalian cells [584,585]. This 1,3-β-d-glucan, an essential cell wall polysaccharide, forms a fibril of three helically entwined linear polysaccharides and provides structural integrity for the fungal cell wall [627,628].

Echinocandins inhibit hyphal tip growth, converting the mycelium into small clumps of cells, but the older septated cells with little glucan synthesis are not killed [629]. Therefore the echinocandin activity endpoint is morphologic change, not in vitro medium clearing. Echinocandins are generally fungicidal in vitro against *Candida* species, although not as rapidly as amphotericin B [556,584], but appear to be fungistatic against *Aspergillus* [630]. As a class these agents are not metabolized through the CYP enzyme system, but through a presumed *O*-methyltransferase, lessening some of the drug interactions and side effects seen with the azole class. The echinocandins appear to have a prolonged and dose-dependent fungicidal antifungal effect on *C. albicans* compared with the fungistatic fluconazole [631].

Three compounds in this class (caspofungin, micafungin, and anidulafungin) are FDA-approved for use in adults. Few studies have evaluated the use of echinocandins in children; most constitute early phase I/II safety and pharmacokinetic studies. Because neonates with candidemia often suffer from disseminated disease in the central nervous system, which is associated with neurodevelopmental impairment, dosing of antifungal agents in this population should target the central nervous system.

An experimental rabbit model of hematogenous *Candida* meningoencephalitis in which micafungin was used as a prototype echinocandin suggests that doses of 8 mg/kg/day are necessary to achieve maximal microbicidal activity in the central nervous system parenchyma of rabbits [574]. When these data are extrapolated to the neonatal population using simulation techniques, the lowest fungal burden in the neonatal central nervous system parenchyma is achieved with micafungin doses of 10 to 15 mg/kg/day [574].

## Caspofungin

### Pharmacokinetic Data

Caspofungin (Cancidas; Merck Co., Whitehouse Station, N.J.) is a fungicidal, water-soluble, semisynthetic derivative of the natural product pneumocandin $B_0$ [632]. It has linear pharmacokinetics [633], is hepatically excreted with a β-phase half-life of 9 to 10 hours in adults [634], and has uncommon adverse effects [615]. Parenteral administration is preferred due to the low bioavailability when administered orally. It is not metabolized by the CYP isozyme system, and the rate of killing for caspofungin in time-kill studies is greater than that of amphotericin B, which does not require cell growth for activity [627].

There is no known maximal tolerated dose and no toxicity-determined maximal length of therapy. The usual course is to begin with a "load" followed by a lesser daily dose. PK appears slightly different in children compared with adults, with caspofungin levels lower in smaller children and with a reduced half-life [635]. PK projections suggest that dosing at 50 mg per $m^2$ appears to be more appropriate in children rather than using 1 mg/kg/day [636]. The kinetics in young infants are not well described, especially at dosages that should be used to clear central nervous system infections. Caspofungin given 25 mg/$m^2$ is thought to provide similar exposure to 50 mg/$m^2$ given to adults; however, this exposure is unlikely to clear central nervous system infections in young infants. Thus a recommended dosage cannot be provided from these data [637].

### Safety

1,3-β-D-glucan is a selective target present only in fungal cell walls and not in mammalian cells; therefore, the echinocandins are rarely toxic in humans [627]. There appears to be no apparent myelotoxicity or nephrotoxicity with the agent [636,638,639].

### PK-PD and Clinical Implications

Caspofungin was approved by the FDA in February 2001 for refractory aspergillosis or intolerance to other therapies, and in January 2003 was approved for candidemia and various other sites of invasive *Candida* infections in adults. In a multicenter trial of 239 patients with invasive candidiasis, 73.4% of patients who received caspofungin had a favorable response at the end of therapy, compared with 61.7% in the amphotericin B group [640]. Mortality was similar in both groups, and the proportion of patients with drug-related adverse events was higher in the amphotericin B group.

Caspofungin in newborns has been used off-label as single or adjuvant therapy for refractory cases of disseminated candidiasis. A study from Costa Rica reported the use of caspofungin (0.5 to 1 mg/kg/day for the first 2 to 3 days and 1 to 2 mg/kg/day for the remaining of the course) among 10 neonates (mean gestational age 33.5 ±1.77) with refractory disseminated candidiasis; all patients had a sterile blood culture within 3 to 7 days of starting caspofungin and the drug was well tolerated [641]. Through a retrospective chart review, another center identified 13 cases of neonates [median gestational age 27 weeks (range, 24 to 28)] treated with caspofungin (1 to 1.5 mg/kg/day) for refractory disseminated candidiasis; 11 of the infants achieved blood sterilization within a median of 3 days (range, 1 to 21). However, all but 3 patients had their intravascular lines removed before the onset of caspofungin therapy [642]. In this cohort, two patients died within 2 days of starting caspofungin; one patient developed severe thrombophlebitis after the initial dose; two patients had hypokalemia while on caspofungin; and four patients had a greater than threefold elevation of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) [642].

Additional studies of caspofungin in the pediatric population are necessary to assess its efficacy. In addition, pharmacokinetic studies in neonates are needed before the widespread use of this antifungal agent in the nursery.

## Micafungin

### Pharmacokinetic Data

Micafungin (Fujisawa Healthcare, Inc., Deerfield, Ill.) is an echinocandin lipopeptide compound [643] with a half-life of approximately 12 hours. There are dose-independent linear plasma pharmacokinetics with the highest drug concentrations detected in the lung, followed by the liver, spleen, and kidney. Micafungin (like the other echinocandins) does not penetrate the CSF [644], but levels were detected in the brain tissue, choroidal layer, meninges, and cerebellum in an experimental rabbit animal model [574]. The product therefore can be considered in premature and young infants (see "Meningoencephalitis" section). Time-kill study of micafungin against

*Candida* species demonstrated potent fungicidal activity against most isolates, including a concentration-dependent postantifungal effect [645].

The pharmacokinetics of micafungin have been well studied in young infants, perhaps more thoroughly than any other antifungal agent as of this writing. A phase I, sequential and single-dose (0.75, 1.5, and 3.0 mg/kg) study of intravenous micafungin in 18 premature infants (mean gestational age 26.4 ± 2.4 weeks) weighing more than 1000 g showed that micafungin pharmacokinetics in preterm infants was linear; premature infants displayed a shorter half-life (8 hours) and a more rapid rate of clearance (approximately 39 (mL/hr)/kg) compared with published data in older children and adults [646]. In this study, an additional 4 infants weighing less than 1000 g received 0.75 mg/kg/day of micafungin and demonstrated shorter mean half-life (5.5 hours) and more rapid mean clearance per body weight (79.3 ±12.5 (mL/hr)/kg) when compared with the heavier infants [646]. These results suggest that young infants may require higher micafungin doses when compared with older children and adults. Data from 12 premature infants (mean birth weight and gestational age 851 g and 27 weeks, respectively) suggests that a micafungin dose of 15 mg/kg/day achieves similar exposures (mean area under the curve 437.5 (±99.4) mg*hr/L) to adults receiving 5 mg/kg/day [647]. Micafungin doses of 7 to 10 mg/kg/day administered to 13 premature infants (mean birth weight and gestational age 1449 (±1211) g 27.3 (±4.68) weeks, respectively) provided adequate exposure (median area under the curve of 258.1 to 291.2 mg/hr/L) to treat central nervous system candidiasis [648].

### Safety

The safety profile of micafungin is optimal when compared with other antifungal agents [1]. In clinical trials of micafungin, patients have demonstrated fewer adverse events compared with liposomal amphotericin B and fluconazole. The most common adverse events were related to the gastrointestinal tract (i.e., nausea, diarrhea). Hypersensitivity reactions associated with micafungin have been reported and 5% of patients receiving the product may develop liver enzyme elevation. Hyperbilirubinemia, renal impairment, and hemolytic anemia related to micafungin use have also been identified in postmarketing surveillance of the drug. The most common adverse events in a phase I micafungin study of 77 children (2 to 17 years of age) with fever and neutropenia were diarrhea (19.5%), epistaxis (18.2%), abdominal pain (16.9%), and headache (16.9%) [649]. Micafungin has very few drug interactions; however, when administered simultaneously it increases overall exposure (AUC) of sirolimus (21%), nifedipine (18%), and itraconazole (22%).

### PK-PD and Clinical Implications

A pediatric substudy (n = 106, ages 0 to 16 years including 14 neonates) was conducted between 2003 and 2005 as part of a double-blind, randomized, multinational trial comparing micafungin (2 mg/kg/day) with liposomal amphotericin B (3 mg/kg/day) for first-line treatment for invasive candidiasis [650]. Treatment success was defined as clinical and mycologic response at the end of therapy. The median duration of study drug administration was 15 days for micafungin (range, 3 to 42 days) and 14.5 days for liposomal amphotericin B (range, 2 to 34 days). In a modified intent-to-treat analysis, the rate of overall treatment success was similar for micafungin (72.9%, 35/48) when compared with liposomal amphotericin B (76.0%, 38/50), with an adjusted difference between treatment groups of −2.4 (95% CI 20.1, 15.3) when stratified by neutropenic status. However, when stratified by age group, liposomal amphotericin B outperformed micafungin in all age groups except for the neonatal group [650]. This observation could be related to the low micafungin dose used in this trial. In general, micafungin was better tolerated than liposomal amphotericin B as evidenced by the fewer adverse events that led to discontinuation of therapy [650].

## Anidulafungin

### Pharmacokinetic Data

Anidulafungin (Pfizer) is a semisynthetic terphenyl-substituted antifungal derived from echinocandin B, a lipopeptide fungal product [651]. It has linear pharmacokinetics with the longest half-life of all the echinocandins (approximately 18 hours) [652] and has shown fungistatic or fungicidal activity in different settings [653]. Analysis in healthy rabbits revealed linear PK with dose-proportional increases in AUC [654]. Neither end-stage renal impairment, dialysis, nor mild to moderate hepatic failure changes the pharmacokinetics of anidulafungin in patients [655].

Tissue concentrations after multiple dosing were highest in lung and liver, followed by spleen and kidney, with measurable concentrations in the brain tissue. The PK showed approximately sixfold lower mean peak concentrations in plasma, and twofold lower AUC values compared with values with similar doses of caspofungin and micafungin.

There is only one study evaluating the PK of anidulafungin in children 2 to 17 years, and none in young infants [656]. The current anidulafungin formulation requires reconstitution with 20% dehydrated alcohol, therefore, its safety and PK profile in infants younger than 2 years is being evaluated in a new formulation that does not contain alcohol.

### Safety

Anidulafungin has an excellent safety profile and appears to be well tolerated [657]. A phase I study reported anidulafungin to be well tolerated in 29 healthy volunteers, with the highest dose cohort experiencing transient liver function test elevations that exceeded twice the upper limit of normal [658]. In a separate study, 12 subjects with mild or moderate hepatic impairment did not cause clinically significant changes in the PK parameters of anidulafungin [659]. However, in patients with severe hepatic impairment, the plasma concentrations of anidulafungin are decreased and plasma clearance increased [660]. In a study of 25 neutropenic children receiving anidulafungin as empirical therapy, rare adverse events included facial erythema and rash, elevation in serum blood urea nitrogen, and fever and hypotension [656].

### PK-PD and Clinical Implications

Clinical trials with anidulafungin are ongoing. A phase III, randomized, double-blind study in adult patients with invasive candidiasis showed that anidulafungin was not inferior to fluconazole in the treatment of invasive candidiasis [661]. The frequency and types of adverse events were similar in the two groups [661]. Neonatal and pediatric formulations and subsequent studies are needed.

CHAPTER 38

# Prevention of Fetal and Early Life Infections Through Maternal–Neonatal Immunization

**James E. Crowe, Jr.**

CHAPTER OUTLINE

## OVERALL PRINCIPLES

Vaccination has been the most effective medical intervention in the modern era. Historically, the focus on vaccine development and implementation programs has been on preventing infectious diseases during infancy and early childhood. The current vaccine schedule for early childhood is replete with dozens of inoculations with an array of safe and effective vaccines that have dramatically reduced the incidence of many previously formidable childhood infectious diseases. Close review of the schedule, however, reveals that most vaccines are clustered in the 2 months to 15 months age group, while there is a paucity of approved vaccines for the neonatal period (Figure 38–1). Safe and effective vaccination of pregnant women and neonates is difficult to achieve, but clearly is now an important target of development. Some of the major pathogens of the neonatal period, such as Group B streptococcus sepsis and meningitis and respiratory syncytial virus bronchiolitis and pneumonia, remain neonatal plagues that can only be addressed by new strategies.

A number of fundamental general principles have been defined through our experience in childhood vaccination programs. First, the usual goal of vaccination is to prevent disease, rather than to induce sterilizing protection against infection. In fact, most licensed vaccines do not completely prevent infection. Eradication of microorganisms in the population is a very difficult goal, whereas excellent protection against severe disease is often achievable. Second, while vaccines generally benefit the individual being immunized, additional public health benefits are often observed when herd immunity is induced in a previously susceptible population. This is especially important for protecting neonates, since there often is insufficient time to induce an adequate immune response for protection in the early weeks of life, and vaccines may not be safe, tested, or immunogenic in this age group. Protecting all of the household contacts and caregivers against infection is currently the most feasible approach for protection of neonates against most diseases. Third, the mechanism by which many vaccines induce protection is poorly understood. Generally current vaccine development programs are accomplished using correlates of protection rather than definitive knowledge of mechanism. A correlate of protection is typically a serologic test with an estimated cutoff of protection that allows comparison of the relatively common data on immunogenicity for different vaccines or vaccine preparations, in contrast to efficacy data, which are difficult to achieve without large numbers of subjects. Examples of correlates of protection that have been established by historical practice are summarized in Table 38–1. Finally, there is significant variation in response to vaccines among individuals that is poorly understood. Responses are affected by many factors such as age, immune status, nutritional status, genetic polymorphisms, and environmental exposures.

*Disclosure:* This chapter is meant to review the principles of vaccination, and many specific indications, practices, and recommendations are discussed below that were current at the time of writing. Vaccine practice is, however, a constantly changing enterprise. Practitioners should consult the vaccine package inserts for FDA-approved uses, and the relevant current documents of the regulatory and advisory bodies for up-to-date information. The recommendations and guidelines of the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) are regularly updated on the website www.cdc.gov. The ACIP is the only entity in the federal government that makes such recommendations. The American Academy of Pediatrics also issues guidelines, as published in notices in the Academy journal *Pediatrics*, and in the periodic handbook called the *Red Book*.

## OBSTACLES TO NEONATAL VACCINATION

To date, there are many vaccines for infancy and early childhood; however, very few vaccines have been successfully implemented in the neonatal period. A large number of obstacles make it difficult to establish a safe and effective neonatal vaccination program (Table 38–2).

DOI: 10.1016/B978-1-4160-6400-8.00038-9

## Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2010

For those who fall behind or start late, see the catch-up schedule

| Vaccine ▼ Age ► | Birth | 1 month | 2 months | 4 months | 6 months | 12 months | 15 months | 18 months | 19–23 months | 2–3 years | 4–6 years |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Hepatitis B[1] | HepB | HepB | | | | | HepB | | | | |
| Rotavirus[2] | | | RV | RV | RV[2] | | | | | | |
| Diphtheria, Tetanus, Pertussis[3] | | | DTaP | DTaP | DTaP | see footnote[3] | DTaP | | | | DTaP |
| *Haemophilus influenzae* type b[4] | | | Hib | Hib | Hib[4] | Hib | | | | | |
| Pneumococcal[5] | | | PCV | PCV | PCV | PCV | | | | PPSV | |
| Inactivated Poliovirus[6] | | | IPV | IPV | | | IPV | | | | IPV |
| Influenza[7] | | | | | | | | Influenza (Yearly) | | | |
| Measles, Mumps, Rubella[8] | | | | | | MMR | | see footnote[8] | | | MMR |
| Varicella[9] | | | | | | Varicella | | see footnote[9] | | | Varicella |
| Hepatitis A[10] | | | | | | | HepA (2 doses) | | | HepA Series | |
| Meningococcal[11] | | | | | | | | | | MCV | |

Range of recommended ages for all children except certain high-risk groups

Range of recommended ages for certain high-risk groups

This schedule includes recommendations in effect as of December 15, 2009. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Considerations should include provider assessment, patient preference, and the potential for adverse events. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations: **http://www.cdc.gov/vaccines/pubs/acip-list.htm**. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS) at **http://www.vaers.hhs.gov** or by telephone, **800-822-7967.**

1. **Hepatitis B vaccine (HepB).** (Minimum age: birth)
   **At birth:**
   - Administer monovalent HepB to all newborns before hospital discharge.
   - If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
   - If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

   **After the birth dose:**
   - The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks. The final dose should be administered no earlier than age 24 weeks.
   - Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg 1 to 2 months after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).
   - Administration of 4 doses of HepB to infants is permissible when a combination vaccine containing HepB is administered after the birth dose. The fourth dose should be administered no earlier than age 24 weeks.
2. **Rotavirus vaccine (RV).** (Minimum age: 6 weeks)
   - Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks 0 days or older.
   - The maximum age for the final dose in the series is 8 months 0 days
   - If Rotarix is administered at ages 2 and 4 months, a dose at 6 months is not indicated.
3. **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).** (Minimum age: 6 weeks)
   - The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
   - Administer the final dose in the series at age 4 through 6 years.
4. ***Haemophilus influenzae* type b conjugate vaccine (Hib).** (Minimum age: 6 weeks)
   - If PRP-OMP (PedvaxHIB or Comvax [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
   - TriHiBit (DTaP/Hib) and Hiberix (PRP-T) should not be used for doses at ages 2, 4, or 6 months for the primary series but can be used as the final dose in children aged 12 months through 4 years.
5. **Pneumococcal vaccine.** (Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])
   - PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
   - Administer PPSV 2 or more months after last dose of PCV to children aged 2 years or older with certain underlying medical conditions, including a cochlear implant. See *MMWR* 1997;46(No. RR-8).
6. **Inactivated poliovirus vaccine (IPV)** (Minimum age: 6 weeks)
   - The final dose in the series should be administered on or after the fourth birthday and at least 6 months following the previous dose.
   - If 4 doses are administered prior to age 4 years a fifth dose should be administered at age 4 through 6 years. See *MMWR* 2009;58(30):829–30.
7. **Influenza vaccine (seasonal).** (Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])
   - Administer annually to children aged 6 months through 18 years.
   - For healthy children aged 2 through 6 years (i.e., those who do not have underlying medical conditions that predispose them to influenza complications), either LAIV or TIV may be used, except LAIV should not be given to children aged 2 through 4 years who have had wheezing in the past 12 months.
   - Children receiving TIV should receive 0.25 mL if aged 6 through 35 months or 0.5 mL if aged 3 years or older.
   - Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.
   - For recommendations for use of influenza A (H1N1) 2009 monovalent vaccine see *MMWR* 2009;58(No. RR-10).
8. **Measles, mumps, and rubella vaccine (MMR).** (Minimum age: 12 months)
   - Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
9. **Varicella vaccine.** (Minimum age: 12 months)
   - Administer the second dose routinely at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
   - For children aged 12 months through 12 years the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
10. **Hepatitis A vaccine (HepA).** (Minimum age: 12 months)
    - Administer to all children aged 1 year (i.e., aged 12 through 23 months). Administer 2 doses at least 6 months apart.
    - Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits
    - HepA also is recommended for older children who live in areas where vaccination programs target older children, who are at increased risk for infection, or for whom immunity against hepatitis A is desired.
11. **Meningococcal vaccine.** (Minimum age: 2 years for meningococcal conjugate vaccine [MCV4] and for meningococcal polysaccharide vaccine [MPSV4])
    - Administer MCV4 to children aged 2 through 10 years with persistent complement component deficiency, anatomic or functional asplenia, and certain other conditions placing tham at high risk.
    - Administer MCV4 to children previously vaccinated with MCV4 or MPSV4 after 3 years if first dose administered at age 2 through 6 years. See *MMWR* 2009;58:1042–3.

The Recommended Immunization Schedules for Persons Aged 0 through 18 Years are approved by the Advisory Committee on Immunization Practices (**http://www.cdc.gov/vaccines/recs/acip**), the American Academy of Pediatrics (**http://www.aap.org**), and the American Academy of Family Physicians (**http://www.aafp.org**).

Department of Health and Human Services • Centers for Disease Control and Prevention

**FIGURE 38–1 Recommended Immunization Schedule for Persons Aged 0 Through 6 Years-United States, 2010** This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 15, 2 for children aged 0 through 6 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.The Recommended Immunization Schedule for Persons Aged 0 Through 18 Years are approved by the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/recs/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org). Department of Health and Human Services, Centers for Disease Control and Prevention.

**TABLE 38–1** Selected Correlates of Protection for Common Childhood Vaccines*

| Vaccine | Type of Test | Correlate of Protection | Reference(s) |
|---|---|---|---|
| Diphtheria | Toxin neutralization | 0.01–0.1 International Units (IU)/mL | [101] |
| Hepatitis A | Enzyme-linked immunosorbent assay (ELISA) | 10 mIU/mL | [102] |
| Hepatitis B | ELISA | 10 mIU/mL | [103] |
| *Haemophilus influenzae* type b polysaccharides | ELISA | 1 μg/mL | [104] |
| *H. influenzae* type b conjugate | ELISA | 0.15 μg/mL | [105] |
| Influenza virus | Hemagglutination inhibition | 1:40 dilution | [106] |
| Measles | Microneutralization | 120 mIU/mL | [107] |
| Pneumococcus | ELISA; opsonophagocytosis | 0.20–0.35 μg/mL (for children); 1:8 dilution | [108,109] |
| Polio | Serum neutralizing | 1:4 to 1:8 dilution | [110] |
| Rubella | Immunoprecipitation | 10–15 mIU/mL | [111,112] |
| Tetanus | Toxin neutralization | 0.1 IU/mL | [113] |
| Varicella | Serum neutralizing; ELISA | 1:64 dilution; 5 IU/mL | [114,115] |

**Modified from Table 4 in reference 116, Plotkin SA. Vaccines: correlates of vaccine-induced immunity. Clin Infect Dis 47:401–409, 2008.*

**TABLE 38–2** Obstacles to Safe and Effective Vaccination of Neonates and Young Infants

| ***Safety Concerns*** |
|---|
| Occult or late presentation of congenital immunodeficiency |
| Occurrence of sudden infant death syndrome during this period |
| Presentation of developmental delay and neurologic syndromes during this period |
| Increased risk of intussusception with gut inflammation at young age |
| Increased risk of wheezing with provocation due to high-resistance airways |
| Need for medical workup for sepsis/meningitis when neonates present with fever without localizing symptoms |
| ***Immunologic Immaturity*** |
| Antibody genes lacking somatic mutations |
| Poor magnitude of antibody immune responses |
| Poor quality of antibody immune responses |
| Poor durability of antibody responses |
| Cytokine bias in response to infection (low Th1/Th2 ratio) |
| Low levels of complement |
| Inability to respond to polysaccharides |
| Concern for inducing tolerance |
| Antibody-mediated suppression of humoral responses caused by transplacentally-acquired maternal antibodies |
| Interference by concomitant exposure to antigens from other infections, environmental antigens, or vaccine antigens |

## Safety Concerns

The Hippocratic principle *primo non nocere*, first do no harm, is the supreme driving principle in all vaccination programs, but even more so in the development of neonatal vaccines. Many events and factors that occur during the neonatal period can complicate the interpretation of vaccine safety at this age. The population at risk for birth defects is estimated to be about 3% or 4%, and not all of these defects are fully apparent at the time of birth. There is a strong trend in the United States to discharge neonates from hospitals and birthing centers before 24 hours of age. If a defect was present at birth but not detected until later, it might be falsely linked to a vaccine given to the neonate. Many if not most congenital immunodeficiencies do not declare themselves this early in life. In some areas of the world, a high percentage of infants are infected with HIV, but this status is not known at the time of birth. Live virus vaccines and the live mycobacterium BCG, while generally effective, are usually contraindicated in immunodeficient individuals. Other types of congenital defects MANIFEST during early infancy, a time in which many vaccinations are given. For instance, many neurologic disorders, including seizure disorders and neurodegenerative diseases, MANIFEST in the first few months of life. Many cardiopulmonary disorders, for instance cyanotic heart disease or cystic fibrosis, do not cause symptoms in the neonatal period. Sudden infant death syndrome also occurs early in life during the target period of vaccination. The cause of this fatal disorder is not well understood; therefore it is very difficult to assess the risk of exacerbation of SIDS by infection or vaccination. A large number of physiologic changes occur during the first few months of life. Young infants possess airways with very small diameters, which exhibit very high resistance especially during airway inflammation. Therefore, young infants are prone to wheezing with relatively minor provocation. Infants are obligate nose breathers. Therefore, a vaccine that has the potential to cause an increase in nasal secretions leading to nasal obstruction, such as live attenuated respiratory virus vaccines, can interfere with feeding, which is a significant problem at this age. Also, infants are susceptible to intestinal intussusception during inflammation of the gastrointestinal tract.

There are also medical factors that complicate the evaluation of vaccines in this age group. Infants in the first two months of life who exhibit fever without localizing symptoms generally undergo a complete medical workup for

sepsis and meningitis. A vaccine that causes even a low rate of fever in this age group will be associated with a large number of expensive and unnecessary medical workups.

## Immunologic Immaturity

Neonates are clearly in transition in their immunologic development as they move from a sterile environment enveloped in the placenta, through the birth canal, into a world with vast numbers of environmental and microbial exposures. Generally it is thought that fetal immune systems are regulated in utero to avoid robust innate and adaptive immune responses to self-antigens or to maternal antigens that cross the placenta. Mouse models suggest that fetuses can be tolerized to antigens following in utero exposure, while human studies are more limited. Suppressive T regulatory cells in the fetus are generated against noninherited maternal antigens, and these cells establish functional tolerance to foreign antigens present during development in utero. For instance, one study observed T regulatory cells in the lymph nodes of fetal products of conception at 18 to 22 weeks of gestation that promoted maternal microchimerism (presence of maternal cells in the fetus) in 15 out of 18 lymph node samples [1]. Foreign antigens clearly do cross the placenta [2,3]. Some human studies suggest that fetal adaptive immune responses to nonself antigens are relatively intact [4–7]. Overall, the evidence suggests that the fetal immune system promotes a relatively high level of tolerance, but it is not devoid of functional activity.

Following parturition, a rapid transition must be made to deal with new antigens from food, the environment, and commensal bacteria, and to differentiate them from harmful micro-organisms. It is likely that this transition takes time, and that human neonates still exhibit some features of predisposition to tolerance, associated with persistence of long-lived T regulatory cells [1] and significant evidence of B cell tolerance [8]. Theoretical concerns are sometimes raised that exposure to antigens early in life during a phase when the immune milieu exhibits a residual tolerogenic status might result in the infant becoming *less* well able to respond to the antigen rather than achieving immunologic priming for memory.

Neonates tend to make poor immune responses following infection or vaccination, both in terms of quantity and quality. The magnitude of antibody responses, as measured by serology, is reduced. The time to peak titer is often delayed by a month or more, compared with the response of older children. The function of the antibodies is low, for example the neutralizing activity of antiviral antibody responses, suggesting that neonates secrete antibodies that bind but do not kill viruses. And the durability of the antibody response made early in life is poor. Young infants who are demonstrated to be infected with a virus early in life, as evidenced by disease and virus shedding, may seroconvert in the months following infection, but then appear to be seronegative the year following. It is likely that this suggests a neonatal B cell response characterized by differentiation of naïve antigen-specific cells to antibody secreting plasma cells without induction of long-lived plasma cells or significant numbers of memory B cells. The B cells of neonates are markedly predisposed to apoptosis following stimulation, compared with adult cells, because of reduced expression of IL-4 receptor and higher levels of gene expression related to proapoptotic programs [9].

Neonatal mice exhibit skewed antibody gene segment usage compared with adult mice; however, most evidence in human infants suggests that the antibody variable gene repertoire is very similar to that of adults, including microbial-specific B-cell repertoires. The antibody sequences of B cells of infants exhibit mature levels of junctional diversity, including N and P type of insertions, and the lengths of the antibody variable loops (complementarity determining regions) are similar to those of adults [10]. The distinguishing molecular difference between adult and infant antibodies is the striking lack of somatic mutations in infant antibody sequences [10]. The use of germline sequences to encode antibodies to microorganisms early in life leads to the generation of low affinity antibodies [11]. Somatic mutations, which occur in the germinal center during antigen exposure, are the driving molecular force behind antibody affinity maturation and increases in antibody function. It is not clear currently whether the lack of mutations stems from the fact that neonatal B cells are encountering antigen for the first time (as opposed to the secondary responses made by older previously exposed individuals), or whether there are intrinsic B cell defects in affinity maturation. Following stimulation with the CD40 ligand and cytokines (mimicking T helper cell interaction), human cord blood B cells do upregulate the transcription of genes involved in somatic hypermutation including activation-induced cytidine deamidase (AID) and error-prone DNA polymerases [12].

There are also factors extrinsic to B cells that affect antibody responses early in life. T cell responses, while perhaps more robust than B cell responses early in life, exhibit some altered features compared with adult T cells. In particular, neonatal responses generally appear to be reduced in the magnitude of Th1 type cytokines, with relatively preserved levels of Th2 cytokines, leading to an overall Th2-biased response. Undoubtedly the model of Th1 versus Th2 biases in this age group is a gross oversimplification of very complex and highly regulated responses that are skewed early in life in various ways. In addition, professional antigen presenting cells such as dendritic cells and macrophages may exhibit developmental programs that affect the outcome of humoral responses.

There are also extrinsic factors that affect the function of the antibody proteins themselves. For instance, complement protein levels are low in neonates, especially terminal elements of the complement cascade. Complement-fixing antibodies may not be able to induce effective formation of membrane attack complexes when terminal complement components are in short supply. Complement also is necessary for optimal antigen presentation in many cases.

Infants exhibit a particular deficiency in responding to capsular polysaccharides, such as those of pathogenic bacteria including *Neisseria meningitides*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, and others. A functional response to the small repeating units of these carbohydrates is usually not observed until the age of two years, although this deficiency has been overcome with conjugate vaccines, discussed later. (For a more detailed discussion of fetal and neonatal immunity, see Chapter 4.)

## Maternal Antibodies

Antibodies from the mother cross the placenta into the fetus, beginning at about 32 weeks, and increasing until term. The transfer appears to be an active process, mediated by a receptor (FcRn) that specifically transports immunoglobulin G (IgG) but not other immunoglobulin isotypes. In some cases, the IgG titer of antibodies at birth exceeds those of the mother. The transfer is beneficial because the infant becomes effectively passively immunized against all of the pathogens to which the mother had mounted an effective response. Acquisition of these antibodies affords protection against severe disease in many cases, but the antibodies are lost over time. Passively acquired maternal antibodies may, however, interfere with the response of neonates to infection or immunization, a phenomenon termed antibody-mediated immune suppression.

## Interference

In some cases, the suboptimal responses exhibited by neonates may be due to interference caused when multiple exposures, infections, or immunizations occur simultaneously. Combination vaccines have been carefully developed, with an eye toward adding new vaccine antigens in such a way as to maintain effective responses to existing vaccines. However, it is common to observe that addition of new antigens can affect the quantitative response to other components of the vaccine. Forcing multiple exposures early in life could lead to interference [13]. It should be remembered that vaccines are not the only exposures, as neonates are also exposed to a myriad of naturally acquired infections, food and environmental antigens, and allergens. Vaccine antigens, in fact, represent a very small component of the antigen exposures early in life.

## Logistics of Immunization Programs

Immunization programs have to be implemented in the context of an overall public health approach. In many areas of the world, children have the highest rate of access to medical interventions in the newborn period. Investigators interested in global health have often dreamed of a single efficacious vaccination given at birth for all major childhood infections because access to children is highest at birth. However, this goal is not really realistic, given the obstacles outlined above. Therefore, each country has to develop an approach to vaccinating infants that achieves the highest feasible coverage based on local resources, infrastructure, financial commitments, cold chain, and other practical considerations. Even if a vaccine has been shown in definitive clinical trials to be efficacious, the effectiveness of a vaccine in the field often is determined by practical considerations of cost/benefit, adverse event profile, and the clinical relevance to the experience of the practitioner and of parents. While pediatricians in the outpatient setting in the United States generally are strong advocates of proper vaccination, hospital physicians and staff who manage the peripartum period are less acculturated to routine vaccination of neonates. Administration of multiple vaccines to all newborns before discharge after birth would require an infrastructure and culture that is not currently present. Parents play a major role in decision making too, appropriately so. Parents will need to be convinced of the clinical benefit and the safety of any vaccines offered shortly after birth.

# VACCINE STRATEGIES FOR PROTECTING NEONATES AGAINST INFECTION

There are four major vaccination strategies for protecting neonates: (1) maternal immunization during pregnancy, (2) passive immunization with antibodies or immune globulins, (3) active immunization of neonates, and (4) immunization of contacts to prevent transmission.

## Maternal Immunization

Immunization of mothers during pregnancy is an attractive strategy for several reasons. Pregnant women typically are easy to identify, and in many areas of the world there is a high level of access to prenatal care. The principle of maternal immunization is to induce or boost the levels of antibodies against micro-organisms in the mother's serum, causing a quantitative or qualitative enhancement of the IgG isotype antibodies that cross the placenta and circulate in the blood of the fetus. Maternal immunization has been shown to be safe and effective for several diseases, especially tetanus [14–16] and influenza [16–20], has been tested for respiratory syncytial virus [21], and is being tested for pertussis (ClinicalTrials.gov Identifier: NCT00553228).

In 1979, the U.S. Food and Drug Administration (FDA) introduced a classification of fetal risks due to pharmaceuticals given during pregnancy. Pregnancy category A is applied when adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). Pregnancy category B pertains when animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women *or* animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester. Pregnancy category C is assigned when animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. All vaccines that have been licensed by the FDA are categorized as pregnancy category C, except for the quadrivalent human papillomavirus vaccine, which is category B.

## Maternal Immunization to Prevent Tetanus, Diphtheria, and Pertussis

In developed countries tetanus and diphtheria are essentially controlled or eliminated. In the 1970s there was a worldwide push to deliver tetanus diphtheria (Td) vaccine to a broad segment of the population by targeting susceptible pregnant women. These campaigns were highly effective in markedly reducing or eliminating tetanus of the mother and infant in some areas. Still, in the 47 poorest countries in Africa and Asia, an estimated 128,250

babies and up to 30,000 mothers died of tetanus in 2004, according to UNICEF [22]. That agency has set a goal to deliver nearly 400 million doses of vaccine in mothers and infants in an effort to eliminate the disease in these groups by 2012. There does not seem to be any problem with performance or safety of the vaccine in these groups; the shortfall stems simply from implementation.

Pertussis on the other hand has been much more difficult to address. Major reductions in numbers of pertussis cases were accomplished by childhood pertussis vaccination through the middle of the 20th century; however, the disease has been rising in incidence for several decades. It is estimated that hundreds of thousands of cases occur in adults in the United States each year, which places infant contacts at risk. Many feel that the durability of solid vaccine-induced immunity may not extend beyond early adolescence, leaving a susceptible adult and older adolescent population.

Pregnant mothers can be infected with *Bordetella pertussis* and suffer symptomatic respiratory tract disease, spanning from mild to severe. Surprisingly, there is little evidence in the literature that pregnant women are more susceptible to severe disease than other healthy adults. Also, there is little evidence that infection of pregnant mothers is associated with adverse outcomes for the fetus, such as fetal demise or altered development. Therefore the focus of maternal immunization against pertussis is on preventing severe disease in young infants *after* birth.

Most of the deaths due to pertussis occur in infants less than 2 months of age, at a time before routine immunization is initiated. The optimal strategy to protect these young infants is not entirely clear. Immunization of women postpartum could maximize immunity in the mother to prevent the mother from acquiring a new infection and transmitting it to newborns. However, data suggest that mothers are the source of pertussis in less than a quarter of cases [23]. Therefore this strategy may have minimal effect on reducing risk in the first months of life. Immunization in the second or third trimester of pregnancy is of potential benefit to the mother by prevention of disease in her, and induces higher levels of antibodies that can be transferred across the placenta. In the first half of the 20th century, pregnant mothers were commonly immunized with whole-cell pertussis vaccine, and it was clear that third trimester vaccination raised the level of antibodies in infants. Efficacy was not studied or proven in a rigorous way, however. There is the suggestion in clinical and epidemiology surveillance studies that maternal immunization reduces the incidence of disease in infants [24–26]. Tetanus, reduced-diphtheria, acellular pertussis vaccine (TdaP) was licensed for use in adolescents and adults in the United States in 2005. This vaccine is commonly given to pregnant women without evidence of harm to mothers or fetuses. Recent changes in policies of the ACIP recommend that adolescents and adults should receive a single dose of TdaP (instead of a single dose of Td), if their last dose of Td was greater than 2 years ago (instead of greater than 10 years ago). The American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Pediatrics now recommend that women should receive TdaP before pregnancy if possible. However, if immunization is not accomplished before pregnancy, TdaP should be given in the second or third trimester, preferably before 32 weeks gestation, to protect the mothers and to transfer immunity to the fetus [27].

## Maternal Immunization to Prevent Influenza

Immunization of pregnant women against influenza is important for the health of both the mother and the infant. The risk of influenza during pregnancy continues to be underappreciated. Seasonal influenza poses a significant risk to the health of pregnant women during annual winter seasonal epidemics [28,29]. Both the ACIP and the (ACOG) recommend that all pregnant women be immunized during the influenza season. Vaccination is recommended at any gestational age. The indicated vaccine is conventional trivalent inactivated vaccine, given by the intramuscular route in the deltoid muscle. Although an intranasal live attenuated trivalent vaccine is available, that vaccine is not recommended during pregnancy. Immunization during pregnancy has been shown to be safe for both the infant and the mother. Pregnant mothers appear to respond well to inactivated influenza virus vaccination, in a similar manner to nonpregnant women, achieving elevated antiviral antibody titers in both maternal serum and umbilical cord serum [18]. A careful prospective trial in 158 mother/infant pairs suggested that immunization of pregnant women could delay onset or reduce severity of disease in infants [30]. Influenza antibody titers in umbilical cord blood of immunized mothers do achieve protective levels; in fact they can be higher than those of the mother. Higher levels of maternal anti-influenza antibodies are associated with greater and longer protection of infants.

## Maternal Immunization to Prevent RSV Infection

Respiratory syncytial virus (RSV) causes hospitalization of infants for wheezing, pneumonia, or apnea, with a peak incidence at about 6 weeks of age. There appears to be some relative sparing of disease in the first weeks of life, possibly associated with maternal antibodies. It is difficult to contemplate inducing immunity in neonates before this age; therefore investigators have investigated maternal immunization against RSV to increase the titer of virus neutralizing maternal antibodies that cross the placenta. The rationale is that, for every twofold rise in maternal antibodies that could be achieved, infants might be protected for an additional 3 weeks if a conventional IgG antibody half-life of 21 days is observed. A small experimental trial of an RSV subunit protein vaccine has been conducted in pregnant women. The vaccine, an immunoaffinity-purified protein isolated from infected cell culture designated purified protein 2 (PFP-2), was safe but minimally immunogenic in a small trial [21]. The promise of this strategy remains unresolved.

## Measles-Mump-Rubella (MMR) Vaccine During Pregnancy

Women are advised not to receive the MMR vaccine during pregnancy because all components are live viruses. Rubella virus is of particular concern since there is the

theoretical possibility of this live virus vaccine causing congenital rubella syndrome. A number of women have inadvertently received this vaccine while pregnant or soon before conception. The CDC collected data about the outcomes of their births. From 1971–1989, 324 infants were born to 321 women who received rubella vaccine while pregnant and continued pregnancy to term, and no cases of congenital rubella syndrome were identified [31]. Given that the risk to the fetus appears to be negligible, a recommendation suggesting termination of pregnancy following inadvertent immunization is not warranted.

## PASSIVE IMMUNIZATION

Antibodies in the blood of otherwise healthy previously infected adults can be collected in the form of plasma or serum, which can also be fractionated to isolate polyclonal immune globulins. If the collections are performed from large numbers of randomly selected healthy donors and pooled, then the resulting preparation of gamma globulin will contain an average titer of antibodies to microorganisms that is found in the donor population. Administration of antibodies to naïve recipients to confer temporary humoral immunity is termed passive immunization.

A large number of hyperimmune and conventional immune globulins and a monoclonal antibody have been licensed for use in humans (See Table 38–3). Conventional immune globulin is used to treat a number of conditions, including congenital or acquired immunodeficiency, Kawasaki disease, and idiopathic thrombocytopenic purpura, and to provide postexposure prophylaxis for hepatitis A and measles. Donors can be screened by serology to identify subsets of individuals with high functional titers of specific antibodies, enabling polyclonal antibody preparations that are enriched in activity for a specific organism, termed hyperimmune globulin (for example RSV immune globulin) [32]. A large number of immune globulins have been produced, such as preparations for botulism, hepatitis B, tetanus, cytomegalovirus, varicella-zoster virus, rabies virus, and vaccinia-virus. Most of these have been used in neonates.

Immunoglobulins are derived from human blood products, so there is the theoretical risk of transmission of adventitious infectious agents. These products are prepared from plasma by a process called Cohn fractionation, which removes most of the potential adventitious agents and purifies the product. Plasma is treated with ethanol in increasing concentrations up to 40%. The pH is progressively reduced over the course of the fractionation, as is the temperature. Five major fractions are recovered, each containing a specific precipitate. In recent years, preparations have also been treated with a solvent-detergent viral inactivation process that is highly effective [33].

### RSV Immune Globulin and Monoclonal Antibodies

RSV immune globulin was partially effective in preventing hospitalization due to severe RSV [34–36]; however the intravenous route and large volumes needed brought challenges for administration. Subsequently, a neutralizing humanized mouse monoclonal antibody to the RSV fusion protein (palivizumab) was developed and licensed that allowed for intramuscular administration. The efficacy of palivizumab was assessed in a randomized, double-blind, placebo-controlled trial (designated the Impact-RSV Study) in high risk infants, with a 55% reduction in hospitalizations [37]. This antibody is the only monoclonal antibody licensed to date for any infectious disease. An affinity-matured second generation RSV monoclonal antibody (motavizumab) is in late-stage clinical trials [38].

### Hepatitis B Immune Globulin

This immune globulin for intramuscular administration is used to treat babies born to mothers who test positive for hepatitis B surface antigen (HBsAg) (or who have not been screened) with or without hepatitis B e antigen (HBeAg). Infants born to mothers known to be HBsAg-positive should receive hepatitis B immune globulin after physiologic stabilization of the infant and preferably within 12 hours of birth. The hepatitis B vaccine series should be initiated simultaneously, if not contraindicated, with the first dose of the vaccine given concurrently with the hepatitis B immune globulin, but at a different site.

**TABLE 38–3** FDA-Approved Products for Passive Immunization and Immunotherapy

| Disease | Product | Indication |
|---|---|---|
| Infant botulism | Botulism immune globulin (BabyBIG) | Treatment of infant botulism |
| Cytomegalovirus | CMV immune globulin | Prevention or treatment in immunocompromised |
| Hepatitis B Ig | Hepatitis B immune globulin | Postexposure prophylaxis |
| Tetanus | Tetanus immune globulin | Treatment of tetanus infection |
| Varicella (chickenpox) | Varicella-zoster virus immune globulin | Postexposure prophylaxis in high-risk individuals |
| Rabies | Rabies immune globulin | Postexposure prophylaxis (administered with rabies vaccine) |
| Vaccinia (smallpox vaccine) | Vaccinia immune globulin | Treatment of progressive infection |
| Hepatitis A | Pooled human immune globulin | Prevention of hepatitis A infection |
| Measles | Pooled human immune globulin | Prevention of measles infection |
| Congenital/acquired immunodeficiency | Pooled human immune globulin | Treatment of immunodeficiency |
| ITP/Kawasaki disease | Pooled human immune globulin | Treatment of inflammatory state |
| Respiratory syncytial virus | Palivizumab (humanized mouse monoclonal antibody) | Prevention of respiratory syncytial virus disease in high-risk infants |

Women admitted for delivery, who were not screened for HBsAg during the prenatal period, should be tested. While test results are pending, the newborn infant should receive hepatitis B vaccine within 12 hours of birth. If the mother is later found to be HBsAg-positive, the infant should receive hepatitis B immune globulin as soon as possible and within seven days of birth; however, the efficacy of hepatitis B immune globulin administered after 48 hours of age is not known [39]. Testing for HBsAg and anti-hepatitis B surface antigen antibodies is recommended at 12 to 15 months of age for infants who were born to HBsAg-positive mothers and who were immunized and given HBIg at birth. If HBsAg is not detectable and surface antigen specific antibodies are present, the child is considered protected [40].

## Varicella-Zoster Immune Globulin (VZIG)

This hyperimmune globulin has been used to protect high-risk individuals following exposure. VZIG treatment is expected to be most effective when it is initiated as soon as possible after exposure, but it may be effective if administered as late as 96 hours after exposure. Treatment after 96 hours is of uncertain value. Small particle aerosols transmit varicella, so assessing exposure is complex. The CDC has defined what constitutes a "substantial" varicella exposure, with the central concept that direct contact exposure is defined as greater than 1 hour of direct contact with an infectious person while indoors [41]. The onset of varicella in pregnant women from 5 days before to 2 days after delivery is estimated to result in severe varicella infection in about a quarter of those newborn infants, with a high risk of death [42–44]. Although numbers of treated infants are not adequate to determine a rigorous efficacy, VZIG reduced disease. In the UK, surveillance studies suggested the proportion of deaths among neonates infected with varicella decreased from 7% to none after the onset of routine use of VZIG in this setting [45]. In October 2004, Massachusetts Public Health Biologic Laboratories, the only U.S.-licensed manufacturer of VZIG, discontinued manufacturing this product. In February 2006, an investigational VZIG product, VariZIG (made by Cangene in Canada) became available under an investigational new drug application with an expanded access protocol. VariZIG can be requested from an authorized U.S. distributor. Intravenous immune globulin (IVIG) should be the primary means of postexposure prophylaxis among persons at high risk of severe varicella complications if VZIG or VariZIG is not available, according to the CDC's Advisory Committee on Immunization Practices (ACIP).

The uses in infants of VZIG in the past, or VariZIG currently, are outlined in the following, which is excerpted from the former VZIG package insert [46] and the VariZIG recommendations of the CDC ACIP, available at www.cdc.gov.

### Immunocompromised Children

VZIG is recommended for passive immunization of susceptible, immunocompromised children after significant exposure to chickenpox or zoster. These children include those with primary cellular immune deficiency disorders or neoplastic diseases and those currently receiving immunosuppressive treatments.

### Newborns of Mothers with Varicella Shortly Before or After Delivery

VZIG is indicated for newborns of mothers who develop chickenpox within 5 days before or within 48 hours after delivery.

### Premature Infants

Although the risk of postnatally acquired varicella in the premature infant is unknown, it is wise to administer varicella zoster immune globulin to exposed premature infants of 28 weeks of gestation or more if their mothers have a negative or uncertain history of varicella. Premature infants of less than 28 weeks of gestation or birth weight of less than 1000 grams should be considered for VZIG regardless of maternal history since they may not yet have acquired transplacental maternal antibodies.

### Full-Term Infants Less than 1 Year of Age

Mortality from varicella in the first year of life is four times higher than that in older children, but lower than mortality in immunocompromised children or normal adults. The decision to administer VZIG to infants less than 1 year of age should be evaluated on an individual basis. After careful evaluation of the type of exposure, susceptibility to varicella including maternal history of varicella and zoster, and presence of underlying disease, VZIG may be administered to selected infants.

VZIG does not appear to significantly alter the attack rate in healthy neonates who are exposed in utero within 5 days of delivery (30% to 40%), but the rate of complications and fatal outcomes appears to be substantially lower for neonates who are treated with VZIG.

## Cytomegalovirus Immune Globulin

This preparation is a purified immunoglobulin for intravenous administration derived from pooled adult human plasma selected for high titers of antibody for cytomegalovirus (CMV) [47]. It is generally used for the prophylaxis of cytomegalovirus disease associated with transplantation of kidney, lung, liver, pancreas, and heart in older subjects. Only limited information is available about the use of CMV-IGIV in pregnancy or the neonatal period, and more study is needed to more fully evaluate the possible benefits and risks of passive immunization with CMV-IGIV in such situations. This hyperimmune globulin has been given to a limited number of pregnant women with primary CMV infection in an attempt to treat or prevent congenital CMV infection. There is some evidence from a prospective, uncontrolled study that administration of CMV-IGIV to pregnant women with confirmed primary CMV infection and with CMV-positive amniotic fluid may decrease the risk of symptomatic congenital CMV disease in their infants; however, this treatment is considered experimental at this time.

## Botulinum Immune Globulin

Infant botulism is a form of human botulism caused by ingestion of *Clostridium botulinum* spores that colonize and grow in the infant's large intestine, resulting in the secretion of botulinum neurotoxin into the intestine. The toxin can cause flaccid paralysis with respiratory

and feeding failure. Botulinum immune globulin is an orphan drug product with high titers of antibodies against botulinum toxin for intravenous administration that is indicated for the treatment of patients below 1 year of age with infant botulism caused by toxin type A or B. The approach, using isolation of immune globulin from the plasma of donors immunized with pentavalent (ABCDE) botulinum toxoid, was developed by the California Department of Health Services. Treatment within 3 days of admission to hospital shortened mean hospital stay of all (type A and type B) infant botulism patients by several weeks, significantly shortened length of ICU stay, duration of mechanical ventilation, and length of tube feedings [48].

## ACTIVE IMMUNIZATION

Immunization of individuals directly to stimulate adaptive immune responses characterized by memory is termed active immunization. This approach is preferred when feasible because long-lasting responses can be induced by brief medical encounters, without further intervention, or in some cases with periodic boosting.

The general approach to developing an effective vaccine starts with an understanding of pathogenesis and correlates of immunity. For instance, tetanus is caused by a toxin secreted by a bacterium, not by the organism itself, so the licensed vaccine was designed to induce antibodies to the toxin rather than the bacterium. Once the fundamentals of the disease are understood through epidemiology studies and animal model experiments, vaccine candidates are developed and tested in preclinical models, usually including small animals such as mice and then nonhuman primates. Human studies are conducted in phases, with increasing numbers of subjects. Phase I trials establish safety (typically in several dozen subjects), phase II trials investigate dose and expanded safety data collection (typically in hundreds of subjects), phase III trials establish efficacy (typically in many thousands of subjects), and phase IV surveillance is sometimes conducted after licensure. There are a large number of strategies for development of vaccines that have been successful to date (Table 38–4).

**TABLE 38–4** Major Types of Vaccines

- Jennerian approach (use of inoculation with a naturally occurring animal pathogen to induce a cross-protective immune response to a human pathogen); e.g., vaccinia virus (the smallpox vaccine), rhesus rotavirus (withdrawn), human-bovine rotavirus reassortant viruses, Bacillus Calmette-Guérin (BCG; a vaccine against tuberculosis)
- Live attenuated viruses
  - Naturally occurring avirulent isolates; e.g., the Jeryl Lynn strain of mumps virus, poliovirus
  - Cell culture passaged mutants (with in vitro marker, such as cold-adapted, temperature-sensitive, small plaque, or other phenotype); e.g., rubella virus Wistar Institute RA 27/3 strain, influenza, poliovirus, measles and mumps viruses, varicella virus, rotavirus
- Inactivated (killed or disrupted) virus; e.g., influenza, inactivated poliovirus, hepatitis A virus, rabies virus
- Toxoid, a bacterial toxin whose toxicity has been reduced; e.g., diphtheria and tetanus toxoids
  - Chemical treatment
  - Genetic manipulation of toxin sequence
- Subunit proteins
  - Purified from serum, cell or egg culture, or recombinant expression systems such as yeast; e.g., hepatitis B surface antigen, papillomavirus
  - Purified from bacterial culture, *Bordetella pertussis*
- Polysaccharides; e.g., *Haemophilus influenzae* type B, *Streptococcus pneumoniae*, *Neisseria meningitidis*
  - Plain, or conjugated to a protein
- Combined vaccines, e.g., MMR/V, DTaP/Hib/IPV, HepA/B, and others
- Experimental approaches
  - Vectored vaccines, DNA, peptides, mimotopes

### Jennerian Vaccines

The simplest approach, pioneered by Jenner, uses an animal micro-organism to infect humans to induce cross-protective immune responses. This approach was used to develop the smallpox vaccine vaccinia, which was also multiply passaged. BCG is a live mycobacterial strain that is used in many parts of the world as a tuberculosis vaccine during the neonatal period.

In recent years, a modified Jennerian approach has been used in which virus genes from animal viruses have been combined with genes from the matching human virus to create chimeric viruses that retain the authentic human protective antigens, but incorporate animal genes that perform suboptimally during virus replication resulting in attenuation. Since these organisms often replicate in the recipients to some degree, they can often induce both T- and B-cell responses and can be very immunogenic. There are two principal ways that the chimeric vaccines are made. If the virus genome is segmented, then the animal virus and the human virus are used to coinfect cells in culture, and viruses with various combinations of gene origins arise, a process termed reassortment. If the genome is nonsegmented, then the viral genomes are cloned by molecular biology techniques to make a cDNA copy of each genome. By molecular means, these genomes can be manipulated to make chimeras, point mutations, or gene deletions or gene order shuffling. Once the altered cDNA is made, plasmid DNA is used to transfect mammalian cells and generate a live mutant virus, a process termed "virus rescue." The modified Jennerian approach has been successful using genes from nonhuman primate and bovine rotaviruses by reassortment. Bovine parainfluenza virus type 3 has been tested in infants as young as two months [49], and chimeric experimental vaccines for respiratory syncytial virus or human parainfluenza virus type 3 have been developed by rescue from cDNA using the bovine virus backbone [50,51].

### Attenuation of Live Human Viruses

Live viruses have been attenuated in additional ways. Typically, viruses can be multiply-passaged in cell culture, during which attenuated viral variants arise as a consequence of viral polymerase error. Mutation rate (or selection for survival of mutants in culture) can be accelerated by passaging and adapting in cells from a different species (resulting in "host range restriction" mutations), passaging in the presence of chemical mutagens that cause missense mutations in the virus genomes,

or selecting for an in vitro phenotype such as cold-adaptation, temperature sensitivity, or small plaque phenotype (for instance the live attenuated trivalent influenza vaccine). Vaccines for poliovirus, measles, rotavirus, rubella, and others have been derived in this way. In some cases, investigators have isolated naturally attenuated or avirulent virus strains from human subjects that can be used as vaccines with their native sequence. Vaccines for mumps and polio virus have been derived in this manner. Six experimental live attenuated vaccine candidates for respiratory syncytial virus made in this way have been tested in clinical trials [52–57]. A live attenuated vaccine candidate for parainfluenza type 3 (the main cause of croup in infants) was developed by multiple passaging in cell culture (designated *cp*45, because it had been cold-passaged 45 times in culture) and has been studied in infants and found to be immunogenic [58]. A phase II trial has been conducted with combined experimental vaccines for respiratory syncytial virus and for parainfluenza type 3 [59].

## Inactivated Vaccines

Growing organisms in culture in the laboratory followed by inactivation is a simple approach that has been dramatically successful for some organisms. Organisms can be inactivated by beta propiolactone, formalin, UV irradiation, and other techniques. The Salk polio vaccine had a dramatic effect on polio epidemiology when implemented. Similar efforts with influenza led to the development of the inactivated trivalent influenza vaccine that is the mainstay of current prevention against influenza disease. Excellent inactivated vaccines also have been developed for hepatitis A and rabies virus. This approach is not without its potential problems, however. If a virulent strain is used to produce the virus stock, inadequate inactivation can lead to iatrogenic disease such as occurred in the so-called Cutter incident. A number of children immunized with an inactivated poliovirus vaccine preparation containing inadequately inactivated Mahoney poliovirus developed paralytic poliomyelitis [60]. Also, unexpected adverse events have followed immunization with inactivated vaccines. In the 1960s, a formalin-inactivated RSV vaccine induced enhanced disease in children when they were later exposed to natural infection, resulting in several deaths [61,62]. Similarly, an inactivated measles vaccine induced a response known as “atypical” measles that was associated with giant cell pneumonia and an unusual rash on exposure to wild-type virus.

## Toxoids

Diseases caused by bacterial toxins (generally exotoxins) have been successfully addressed by the development of toxoids. In some manner, the virulence of the toxin is reduced or removed, while preserving the immunogenicity of the resulting protein. Detoxification can be achieved by treating wild-type toxins with chemicals to alter them, or by creating genetic mutant forms of toxin that can be expressed in the laboratory. These vaccines tend to be very immunogenic and effective. Tetanus toxoid and diphtheria toxoid are the prototypes for this approach. Toxoids are also used sometimes as the carrier protein to which polysaccharides are attached in conjugate vaccines.

## Subunit Proteins

The success of inactivated virus vaccines led to the idea that nonreplicating materials could induce protective responses as long as the materials contained the protective antigens (usually the target of protective antibodies) in a conformationally intact presentation. Microbial proteins can be partially or highly purified from whole organism cultures by extraction and purification, or individual proteins can be expressed in a recombinant fashion from DNA copies of the coding region of the protein. Hepatitis B surface antigen (HBsAg), a highly effective vaccine, was originally isolated from the plasma of naturally infected subjects, but now is expressed in *Saccharomyces cerevisiae*. The use of nonreplicating proteins has the advantage that the antigen will not likely cause the disease produced by the microbe; however, inoculation with proteins usually does not induce MHC Class I restricted cytolytic T cells, and the response to subunit proteins is often weak in the absence of adjuvants.

## Polysaccharide Vaccines

Encapsulated bacteria are some of the major pathogens of infancy. Immunity to most of these organisms is mediated by type-specific capsular polysaccharide antibodies. Therefore, immunization with polysaccharides purified from the organism is immunogenic and protective in older individuals. For instance, there is a 23-valent polysaccharide vaccine for protection against invasive disease caused by the pneumococcus. Infants less than 2 years of age, however, do not respond to polysaccharides. Investigators found, however, that conjugation of these polysaccharides to carrier proteins enabled young infants to respond to the immunizations with robust antibody responses to the polysaccharides. The intellectual concept was that the carrier protein would facilitate coupled T helper cell induction by B cells specific for the polysaccharides that process and present peptides from the associated protein, thus inducing T cell help for the response. Interestingly, different carrier proteins exhibit differing performance levels. Now we know that some of these carrier proteins also work in part by stimulating pattern recognition receptors such as Toll-like receptors.

The first conjugate vaccines were aimed at *H. influenzae* type B (Hib), a former major cause of sepsis and meningitis in infancy. The polysaccharide Hib vaccine worked poorly in young children, while the conjugate vaccine has virtually eliminated the disease in the United States. Conjugated vaccines have been developed for *S. pneumoniae* that are effective, but a challenge is to incorporate as many type-specific polysaccharides as possible to cover circulating field strains. The frequency of strains varies in different geographic locations. The current pneumococcal conjugate vaccine, designated PCV7 or Prevnar and containing antigens from serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F, was licensed in 2000 and can be used in children

under the age of 2 years. This conjugate vaccine has been incorporated into the childhood immunization schedule in the United States for infants aged 2 to 23 months. Subjects older than 2 years of age at high risk of disease can be given the 23-valent polysaccharide vaccines (designated PPV23 or PPSV), marketed as Pneumovax or Pnu-Immune. Additional conjugate vaccines are being studied; a 9-valent (PCV9) vaccine provides coverage of the serotypes in PCV7 plus coverage of serotypes 1 and 5, while an 11-valent (PCV11) vaccine provides PCV9 coverage plus serotypes 3 and 7F. A conjugate strategy for a vaccine for older subjects has been developed for four meningococcus subtypes. Quadrivalent meningococcal polysaccharide vaccine (designated MPSV4, Menomune, Sanofi Pasteur) was the only meningococcal vaccine available in the United States until a quadrivalent meningococcal conjugate vaccine (designated MCV4, Menactra, Sanofi Pasteur) was approved for young children in 2007. This vaccine is approved now in subjects aged 2 to 55 years, but is being studied in younger children. Experimental meningococcal conjugate vaccines are being further developed to cover as many types as possible.

## Combination Vaccines

The relatively large number of successful childhood vaccines resulted in an inordinate number of needle injections to deliver all recommended vaccines. Therefore a push has been made over the years to combine vaccines to reduce injections, visits, and administration costs. Most childhood vaccines in use today are in fact combination vaccines. Various combinations are possible, and depend in part on the intellectual property and the clinical experience of the manufacturer. Diphtheria and pertussis toxoids are routinely coadministered with pertussis antigens, but Hib conjugate vaccine and trivalent inactivated poliovirus can be added to this combination. Measles, mumps, rubella, and varicella live attenuated viruses can be coadministered as a single inoculation. Even live or killed poliovirus and live or killed influenza virus vaccines can be considered to be combination vaccines because they each contain three different viruses representing antigenic variants.

When converting vaccines from a monovalent form to a combined form, manufacturers must demonstrate that the combination does not result in interference that reduces the efficacy of any of the components. For instance, the dose of each of the three live poliovirus vaccine strains was adjusted to achieve optimal immunogenicity for each without interference. Often serologic correlates of protection are followed for the purpose of analyzing whether interference occurs. Interpretation of these serologic tests is definitive only when a solid quantitative correlate of protection has been established, which is often lacking.

## Experimental Approaches

A number of additional technologies are being explored for the development of new vaccines. Insertion of heterologous sequences into an attenuated organism is termed using a vectored approach. This approach is common in preclinical development today, using viral vectors such as poxviruses, adenoviruses, alphaviruses, and other organisms. Bacterial vectors such as *Salmonella* and BCG are also under investigation. DNA immunization using plasmid DNAs that encode microbial antigens that are expressed under the control of mammalian promoters is administered by needle injection or by “gene-gun” gold particle-mediated inoculation. These and other approaches are common in the preclinical arena and in phase I healthy adult trials, but they face significant regulatory hurdles before neonatal vaccine trials could be contemplated.

### Adjuvants

Immunologic adjuvants are substances that enhance the magnitude, induction, or durability of antigen-specific immune responses when used in combination with specific vaccine antigens. Typically adjuvants are not antigenic when administered in the absence of vaccine antigens. Historically, there has only been one type of adjuvant licensed for human use, aluminum salts (alum). These inorganic compounds, such as aluminum hydroxide and aluminum phosphate, mediate aggregation and physical deposition effects for the complexed antigens, but they also have additional effects. These and other adjuvants cause inflammatory responses, sometimes mediated by Toll-like receptors and other pattern recognition molecules. This mechanism is a two-edged sword, as untoward effects of inflammation may occur, and alum may skew the cytokine responses to antigen toward a Th2-dominated profile.

Many newer adjuvants are under development; a large number has been tested in adults in the context of experimental HIV vaccine trials. Various classes of new adjuvants include oil-based products, virosomes, and organic molecules such as squalene—QS21 and MF59 adjuvants are being investigated closely. Toll-like receptor agonists are being investigated in an attempt to stimulate the innate immune system in a controlled fashion. Despite the explosion of knowledge of innate immune mechanisms in recent years, incorporation of adjuvants into vaccine development programs is still largely an empirical exercise.

### Route of Inoculation

Various routes of inoculation are used for immunization, depending on the mechanism of action, convenience, and the technology used. Live attenuated viruses intended to induce gastrointestinal tract mucosal immunity (such as rotavirus and poliovirus vaccines) are fed orally. Live attenuated viruses intended to induce respiratory tract mucosal immunity, such as live attenuated influenza vaccine, can be administered as intranasal drops or spray. Live viruses designed to induce high levels of systemic immunity marked by elevated serum levels of antibody, such as measles, mumps, rubella, and varicella, are given by a parenteral route such as intramuscular or subcutaneous. This strategy makes sense because the pathogenesis of systemic diseases such as measles often involves a viremia during which the circulating viruses are susceptible to serum antibodies. Interestingly, the site of intramuscular inoculation (deltoid, gluteus, quadriceps) can affect the immunogenicity of vaccination, so providers should

follow the vaccine package insert to most closely replicate the conditions used in the successful efficacy trials.

### *Timing*

The age of vaccine recipients and presence or absence of passively acquired maternal antibodies greatly affects response to vaccination. The antibody response to measles virus vaccine, for instance, is highly susceptible to inhibition by small amounts of maternal antibodies. Administration of vaccine before 12 months of age is associated with diminished responses in infants due to the presence of passively derived maternal antibodies, and administration before 6 months of age is associated with diminished responses even in infants lacking passively acquired maternal antibodies [63]. Therefore vaccination is optimally initiated after 12 months of life [63]. This plan represents a major problem in developing world environments because the disease often occurs in infants less than 1 year of age. It was reasoned that one effective approach might be to deliver an increased dose of attenuated virus in young infants in an attempt to overcome suppression mediated by maternal antibodies. In 1989, high-titer measles vaccine using the Edmonston-Zagreb strain was recommended by the WHO for use in areas with a high incidence of measles in children younger than 9 months [64]. Three years later, that recommendation was withdrawn because reports from Haiti, Senegal, and Guinea-Bissau suggested an increased incidence of female mortality occurring after administration of the high-titered vaccine [65,66]. The pathogenesis of this process is not fully understood, and the association was not observed in all areas where high-titered vaccine was used. Nevertheless, high-titered vaccine is no longer used.

Many childhood vaccines are initiated in the first weeks or months of life, including DPT and DTaP, polio, Hib, and hepatitis B vaccines. Multiple doses of these vaccines are often required to achieve sufficient immunogenicity and protection early in life. The interval between doses also may significantly affect the immunogenicity of particular vaccines. Often the optimal interval is not known, or cannot be implemented, because most countries develop a standard infant vaccine administration schedule. Having done so, the introduction of new vaccines early in life is typically designed to fit the established visit schedule, such as 2, 4, and 6 months of life in the United States.

### *Birth Dosing*

Most infant vaccines are not actually administered during the neonatal period; however, there are a few notable exceptions. BCG is given in many countries of the world shortly after birth. A series of hepatitis B inoculations can begin shortly after birth as well. Universal immunization with hepatitis B vaccine is principally aimed at preventing sexually transmitted or blood borne disease later in life; however, initiating the series near the time of birth can contribute to the interruption of mother-child transmission in the setting of maternal infection. If a mother is known to be infected, a combination of hepatitis B immune globulin and hepatitis B vaccine is administered at the time of birth.

## SPECIFIC VACCINES FOR INFANTS

### Bacille Calmete Guerin

This organism is a live attenuated *Mycobacterium bovis* vaccine. It is given soon after birth in most countries in sub-Saharan Africa. It is estimated that approximately three quarters of the global birth cohort is immunized near the time of birth with this vaccine. It is not routinely used in the United States. Various substrains and preparations are used in different countries, and the efficacy of the vaccine against infection is questionable. However, there is a consensus that vaccination reduces the most severe forms of tuberculosis, disseminated processes marked by miliary disease or tuberculous meningitis, which among otherwise healthy individuals most commonly occur in children of less than 2 to 4 years of age. There are a large number of studies whose numbers conflict; however, meta-analysis suggests that vaccination prevents about 75% of miliary disease and tuberculous meningitis [67,68]. In contrast, it is not clear that BCG affects pulmonary tuberculosis disease.

The vaccine causes a significant local inflammatory reaction in many cases, but is safe in immunocompetent children. It is estimated that less than 5 in a million healthy children develop disseminated disease with BCG [69], and many of these children prove to have congenital immunodeficiencies. In contrast, a special concern with this live vaccine is that the geographic areas in which it is most used also are areas where HIV infection is especially common and often undiagnosed. As a consequence, universal vaccination of infants results in inoculation of a significant number of infants who will develop HIV infection and AIDS. The risk of disseminated BCG infection and disease is several hundred fold increased in infants with HIV infection (estimated incidence 401 to 1300 per 100,000) [69]. The WHO has now made HIV infection in infants a full contraindication to BCG vaccination [70].

### Diphtheria

*Corynebacterium diphtheriae* is an aerobic gram-positive bacterium which secretes a toxin that inactivates human elongation factor eEF-2, thus inhibiting translation during protein synthesis by human cells. The site of infection, generally the throat, becomes sore and swollen. The toxin can cause damage to the myelin sheaths in the central and peripheral nervous system leading to loss of motor control or sensation. Immunization with diphtheria toxoid has been in widespread use since the 1930s; the vaccine is one of the safest in use. The toxoid can be manufactured from diphtheria toxin treated with formalin to inactivate the toxicity but maintain immunogenicity, and is administered as part of the DPT vaccine beginning at about 2 months. Pertussis toxin (PT) and diphtheria toxin (DT) also have been detoxified genetically by introduction of point mutations that cause a loss of enzymatic activity but retention of binding activity. One mutant DT protein that is a toxoid with a single amino acid mutation at the enzymatic active site, designated $CRM_{197}$, is the protein carrier for a licensed *H. influenzae* type B vaccine.

## Pertussis

*B. pertussis* is a gram-negative coccobacillus which causes an acute respiratory illness with multiple protracted phases. The organism secretes a number of toxins that affect respiratory tract epithelial cells, and also some that have systemic effects such as the promotion of lymphocytosis. The disease is most severe in the youngest infants [71]; however, routine vaccination typically does not begin until age 6 to 8 weeks. The need for inducing herd immunity to reduce disease in the contacts of infants through immunizing healthy adults, adolescents, and pregnant mothers was discussed above. There are two principal types of pertussis vaccines, inactivated organisms ("whole-cell," often abbreviated P) and a formulation that uses antigen fragments derived from the organism ("acellular," often abbreviated aP). Both vaccines are immunogenic and protective, but the acellular vaccine causes about a tenfold lower rate of side effects such as fever or injection site pain and erythema. Most developed countries use acellular pertussis vaccine, but many countries continue to use the whole-cell vaccine because it is cheaper and equally efficacious. The WHO Expanded Program on Immunization (EPI) uses the whole cell vaccine in its vaccination efforts.

It seems to be intuitive that if the most severe disease caused by pertussis occurs in the first months of life, then adding a dose of vaccine near the time of birth might be effective in reducing disease early in life, and indeed this approach has been investigated recently in three relatively small studies of neonatal acellular pertussis vaccination in the United States and Europe [72–74]. Although the protocols and vaccines differed somewhat, it is not clear that adding a birth dose of acellular pertussis vaccine increases immunity to pertussis without interfering with other vaccine responses or the long-term immunogenicity of pertussis vaccine. An Italian study showed that a birth dose of aP vaccine followed by the standard Italian schedule for DTaP vaccination at 3, 5 and 11 months resulted in earlier antibody responses but lower PT IgG levels at 7 to 8 months of age [74]. A U.S. trial studied DTaP administered at birth plus the conventional vaccination schedule at 2, 4, and 6 months. Pertussis antibody levels were similar at 6 months of age in the two groups, but at 7-month levels were significantly lower in the group vaccinated at birth, an effect that was still noted at 18 months of age [72]. A German study of aP vaccine at birth revealed induction of a higher response to pertussis antigens at 3 months of age compared with controls and equivalent pertussis antibody titers at 8 months of age with or without a birth dose [73]. Previous trials with whole-cell pertussis vaccine in this age group also generated data that raised the question of whether inhibition of response is caused by an early dose. More study is needed in this area.

## Tetanus

*Clostridium tetani*, the bacterial cause of tetanus, enters through open wounds from environmental sources and produces a toxin that causes prolonged spasms and tetani. The tetanus toxoid vaccine was developed in 1926. The vaccine is a solution of formaldehyde-deactivated toxin isolated from the bacterium. It also is one of the safest vaccines in use, and is perhaps the most immunogenic vaccine in use in children. Immunization of infants is routinely initiated at 2 months of age.

Neonatal tetanus (tetanus neonatorum) is caused by contamination of the stump of the umbilical cord. The symptoms of the disease often begin in the first 2 weeks of life, well before routine vaccination is initiated at 2 months, and the disease is often fatal. Maternal immunization and clean treatment of the umbilical cord stump are the best approaches to prevention of this disease.

Tetanus of mothers can occur during pregnancy following wound contamination. Most cases of obstetric tetanus occur in the puerperal or postpartum period, however, often after complicated deliveries or surgical or spontaneous abortions [75].

## Poliovirus

There are two types of poliovirus vaccines in use. The first is a trivalent live attenuated vaccine developed by Albert Sabin in the 1950s and licensed in 1961, containing attenuated poliovirus, types I, II, and III, grown in monkey kidney cell tissue culture. This vaccine is administered orally, replicates in the intestine, but does not invade neurons, thus it induces long-lasting intestinal and humoral immunity. Shedding of vaccine viruses in the stool results in transmission of vaccine viruses to close contacts, which has both benefits and risks. The benefit is that many naïve contacts who were not vaccinated themselves become inoculated and immune, thus achieving a high level of herd immunity. For this reason, the live vaccine is preferred in most large-scale eradication efforts in areas where disease still occurs.

Attenuated polioviruses do mutate during replication, however, and lose aspects of attenuation. Rarely (about one case per million doses), these partial revertant viruses cause vaccine-associated paralytic poliomyelitis. The last case of wild-type poliovirus disease acquired in the United States occurred in 1979. For this reason, the United States discontinued use of the live vaccine in 2000. The live vaccine is contraindicated in pregnant women and subjects with HIV infection, other serious immunodeficiencies, or their household contacts.

The other vaccine, inactivated polio vaccine (IPV) is a killed virus preparation, first developed by Salk and licensed in 1955. Killed vaccine induces principally humoral immunity, but still exhibits excellent efficacy against disease. IPV does not have the benefit of causing herd immunity, but also does not transmit virus to contacts and does not cause vaccine-associated paralysis. The enhanced potency IPV vaccine that is in current use has been in use since 1998. It is a component of some combination vaccine formulations.

## Varicella Zoster Virus

Varicella zoster virus (VZV) is spread by the respiratory route by small particle aerosol, and is one of the most infectious agents that affect humans. Before implementation of vaccination, infection was universal in childhood, consisting of a febrile syndrome with vesicular rash. The disease, though often relatively mild, was sometimes complicated by pneumonia, central nervous system effects (including encephalitis), secondary infection such as

bacterial cellulitis or fasciitis, and hemorrhagic conditions. Varicella during pregnancy can have adverse consequences for the fetus and infant of a nonimmune mother, including congenital varicella syndrome. It has been estimated that several dozen cases of this syndrome occurred each year before universal immunization. There was close consideration for many years whether universal vaccination was warranted in the United States because there were only about 100 varicella-associated deaths a year, and it was expected that the vaccine strain would persist, dormant in the sensory-nerve ganglia like the wild-type virus. Further, the durability of protection was not known. Since varicella disease is often more severe in older subjects, concern was raised about the possibility of waning immunity during adulthood leading to more severe disease. Nevertheless, based on an extended experience in Japan and excellent safety and efficacy data, the virus was licensed for universal immunization in the United States in 1995 [76].

This vaccine contains the Oka strain of live, attenuated VZV. The Oka strain was isolated in Japan in the early 1970s from vesicular fluid in a healthy child who had natural varicella and was attenuated through sequential propagation in cell monolayer cultures in the laboratory [77]. The virus in the Oka/Merck vaccine in use in the United States was further passaged in MRC-5 human diploid-cell cultures for a total of 31 passages. The combination MMRV vaccine was licensed in 2005 on the basis of noninferiority of immunogenicity of MMRV compared with MMR and varicella vaccine given at different sites [78]. The ACIP recommends the use of either MMRV vaccine or the separate MMR and varicella vaccines for children at 12 to 15 months of age, and expressed a preference for the MMRV vaccine for the second dose, given at 4 to 6 years of age.

## Measles Virus

The current measles vaccine is a live attenuated strain given subcutaneously. There are numerous strains of attenuated virus that have been developed, and the strains used in the vaccine have varied between countries and over the years in the United States. The live attenuated Edmonston B strain was licensed in 1963 and used until 1975. A further attenuated vaccine called the Schwarz strain was introduced in 1965 and used for a number of years. Finally, a live, further attenuated preparation of the Enders-Edmonston virus strain was developed and licensed in 1968 (designated the "Moraten" strain because it was more attenuated). This is the only measles virus vaccine currently used in the United States. The vaccine is highly immunogenic in seronegative subjects. Maternal antibodies inhibit vaccine immunogenicity in the first year of life. Therefore, vaccination is delayed until 12 to 15 months of age in the United States and other countries of the developed world.

## Mumps Virus

Mumps virus causes a febrile illness most commonly associated with parotitis, but also sometimes more severe conditions including aseptic meningitis. Pregnant women who contract mumps infection during the first trimester of pregnancy suffer an increased risk for fetal death [79], but pregnancies not resulting in fetal demise are not associated with congenital malformations [80]. In the early 1960s, an inactivated vaccine was used, but live attenuated virus has been used exclusively since 1978. The current vaccine strain has an interesting history. The noted virologist Maurice Hilleman isolated the virus from the throat of his daughter, Jeryl-Lynn, and developed it as the vaccine strain. Later studies revealed the vaccine strain is actually a mixture of two strains that have differing genetics and in vitro growth characteristics [81]. The vaccine is typically given as a component of MMR or MMRV vaccine at 12 to 15 months of age. The incidence of mumps in the United States has been remarkably reduced by universal vaccination since the 1960s, especially notable after the widespread use of a second dose of mumps vaccine among U.S. schoolchildren began in 1990. Recent outbreaks in the United States, however, raise the question of whether a new strain or strategy is needed [82].

## Rubella Virus

Rubella virus is a member of the Togaviridae family that is spread by respiratory droplets, causing a mild infection with viremia. The rubella virus vaccine is a live attenuated virus first licensed in 1969. It is given subcutaneously, now usually as a component of MMR or MMRV vaccine, beginning between 12 and 15 months of age. The live rubella virus vaccine currently distributed in the United States, prepared using the RA 27/3 strain grown in human diploid cell culture, was licensed in the United States in 1979. Several strains used previously, including the HPV-77 and Cendehill strains, induced more adverse events and less durable immunity.

The main goal of rubella immunization is prevention of congenital rubella syndrome. There are several approaches that have been used to achieve immunity in women of childbearing age. For many years in the UK, girls were inoculated against rubella in their early teens, as the childhood disease in boys and girls is typically mild and the focus was on prevention of congenital rubella syndrome. In the United States, an alternate strategy was used, that of immunizing all children in an effort to reduce circulation of the virus in the population, and thus the risk of exposure of pregnant women to children with virus shedding. Both strategies showed some effectiveness, but universal immunization proved more effective. Rubella and congenital rubella syndrome have been eliminated in the United States because of high vaccine coverage and high rates of immunity in the population [83].

Rubella vaccine has long been incorporated into the MMR or MMRV combination vaccines for universal immunization of both boys and girls starting at 12 to 15 months, followed by a booster dose at school entry. The WHO also recommends that countries undertaking measles elimination should also take the opportunity to eliminate rubella through the use of measles-rubella (MR) or MMR vaccine in their childhood immunization programs.

## Hepatitis B

Hepatitis B virus causes a potentially life-threatening liver disease that in many cases becomes chronic. Hepatitis B virus is transmitted between people by contact with blood or other body fluids. Children typically acquire hepatitis B infection in one of three ways: (1) Perinatal transmission

from an infected mother at birth, (2) early childhood infections through close interpersonal contact with infected household contacts, or (3) blood transfusion. Hepatitis B vaccines have been available since 1982. The strategy in the United States initially was to target vaccine to health care workers and patients at high risk; however, that strategy was not adequately effective because of poor compliance. Currently, the strategy is that all infants should receive the hepatitis B vaccine. This approach has several benefits. First, universal vaccination typically achieves higher coverage of those later at risk than targeted programs. Second, initiation of immunization near the time of birth interrupts vertical transmission from mother to child. In areas where mother-to-infant spread of hepatitis is common, the first dose of vaccine should be given within 24 hours of birth. When it is known that a mother is actively infected at the time of birth, the baby is treated with both hepatitis B immune globulin and vaccine. The original vaccine was prepared from the plasma of patients infected with hepatitis B, but now the protective antigen, hepatitis B surface antigen, is produced in a recombinant form in yeast.

Apart from the direct metabolic effects of liver dysfunction, chronic infection with hepatitis B also is associated with liver cancer. Therefore the hepatitis vaccine was the first licensed vaccine to prevent cancer.

## Hepatitis A

Hepatitis A is transmitted by the fecal-oral route and causes acute liver disease. Transmission is relatively common in day-care settings. This inactivated vaccine is recommended for all children, starting at 1 year of age. Two single-antigen vaccines are licensed in the United States, and one hepatitis vaccine combined with hepatitis B vaccine. The vaccine is given as a two-dose series.

## Influenza Virus Vaccine

Influenza virus is a respiratory virus spread by large particle aerosol and fomites. This orthomyxovirus circulates in humans in two major types (A and B), with two distinct A subtypes currently causing disease in humans, designated H1N1 and H3N2. Therefore, current seasonal influenza vaccines are trivalent, including A/H1N1, A/H3N2, and B antigens. The virus uses an RNA dependent RNA polymerase to replicate that is error-prone, and each year point mutations occur in the major antigenic proteins hemagglutinin and neuraminidase, a process called antigenic drift. This constant variation in circulating strains requires that new antigens be considered for incorporation into influenza vaccines on an annual basis. Periodically, the segmented genome of this RNA virus reassorts (mixes segments genetically) with a heterologous influenza strain (typically of animal origin), causing a complete change in the hemagglutinin and/or neuraminidase, a process termed antigenic shift. When these shifts occur with a virus that replicates well and transmits well in humans, then pandemics occur. Pandemics are declared by the WHO when a new influenza virus subtype emerges that infects humans, causing serious illness, and the virus spreads easily among humans in more than one world region. Major worldwide pandemics occurred in 1918 (H1N1), 1957 (H2N2), 1968 (H3N2), and most recently in 2009 (novel H1N1).

Two types of influenza vaccines are currently licensed. The first is an inactivated preparation prepared by inactivating wild-type viruses prepared in eggs. The effectiveness of this trivalent vaccine is not entirely clear, but in general is estimated by most experts to be about 70% [84]. The efficacy varies year-to-year based on the accuracy of the match of the prepared vaccine strain antigens (chosen based on prior year data) and the eventual circulating antigens of the current year. The vaccine is most effective against severe disease and hospitalization, but probably also reduces the absolute number of infections.

Seasonal influenza vaccines are indicated for pregnant women of any gestation, and children as young as 6 months of age. Although the vaccine is not licensed for use in neonates, young infants and newborns can benefit greatly from a comprehensive influenza vaccination program if all of the intimate contacts of the infant, such as household contacts and caregivers, can be immunized, achieving a herd immunity effect. Some inactivated influenza vaccines still contain a preservative related to mercury called thimerosal. Concern was raised in the past that thimerosal might be causally related to developmental disorders. In 2004 the Institute of Medicine published a comprehensive review of the question and concluded that there is no evidence of such a relationship [85]. Thimerosal-free inactivated influenza vaccine is available now, however.

The second type of influenza vaccine is a trivalent live attenuated virus suspension that is delivered by nasal spray device. This approach was initially developed in 1960, but took several decades to bring to licensure. The attenuating genes and mutations have been defined, enabling scientists to coinfect new wild-type antigenic variants (drifted strains) in the laboratory with the attenuated strains. Selection methods have been developed to isolate new strains that arise from reassortment of the segmented genomes, such that the new vaccine strains possess the new surface proteins for immunogenicity but the established virus genes encoding the internal attenuating virus proteins. New vaccines need to be prepared each year to address antigenic drift. Live attenuated vaccine has been shown to be highly efficacious, leading to its licensure in 2003 [86,87]. Initially the vaccine was licensed for persons 5 to 49 years of age. In 2007 the FDA approved an expanded label to include children 2 to 5 years of age. A comparative trial of inactivated vaccine and live attenuated vaccine in children 6 to 59 months of age showed that 54.9% fewer cases of cultured-confirmed influenza occurred in the group that received live attenuated vaccine than in the group that received inactivated vaccine [88]. Respiratory tract infection with wild-type influenza virus can cause wheezing. Current studies are investigating whether or not there will be a minor association of live attenuated virus vaccination and wheezing. If safe, this vaccine would benefit younger infants who suffer a high burden of serious disease caused by influenza.

## *Streptococcus pneumoniae* Vaccines

*S. pneumoniae* is a gram-positive encapsulated organism that causes invasive diseases in infants and young children, including meningitis, bacteremia and sepsis, and pneumonia. Disease is caused by dozens of different

types, which are based on the capsular polysaccharide. Immunity is mediated by type-specific antibodies that bind the polysaccharides. Two types of vaccines are available to prevent pneumococcal disease (polysaccharide and conjugate vaccines), but only the conjugate vaccine is used in infants. The polysaccharide vaccine was developed first, with 14-valent vaccine in 1977 and 23-valent vaccine in 1983. Long chains of capsular polysaccharides are collected from inactivated bacteria. Polysaccharide vaccine is indicated for children and adults at high risk, but the vaccine is not effective in children less than 2 years of age. The safety of the vaccine for pregnant women has not been studied carefully; however, adverse consequences have not been reported in newborns whose mothers were vaccinated with pneumococcal polysaccharide vaccine during pregnancy.

A conjugate vaccine was developed that shows a high level of safety and efficacy against invasive disease [89]. The seven serotypes of *S. pneumoniae* that are included in the vaccine (designated types 4, 6B, 9V, 14, 18C, 19F, and 23F) were chosen because they are the strains that most commonly cause serious invasive disease in children. Routinely, the vaccine is given at 2, 4, 6, and 12 to 15 months of age, but it can be given as early as 6 weeks of age. Efforts are underway to increase the number of serotypes in conjugate vaccines, as discussed previously.

## Rotavirus

Rotavirus is the most common cause of dehydrating diarrhea in infants throughout the world. The infection, which is acute and can be treated by rehydration, causes a large number of hospitalizations in the United States and deaths in developing countries. Interestingly, rotavirus infection in healthy full-term neonates often is asymptomatic or results in only mild disease, suggesting a possible short-lived protective effect from passively transferred maternal antibodies [90].

Ongoing worldwide surveillance has revealed a wide diversity of strains causing disease, but it is clear that four or five types are the most common causes of severe disease. Scientists at the National Institutes of Health developed a tetravalent live attenuated vaccine based on a modified Jennerian approach. One of the vaccine components was a rhesus monkey rotavirus (RRV), and the other strains were made by reassorting the genes that determine type with RRV to generate three additional strains. This vaccine showed efficacy against severe disease and was licensed in 1998 [91]. The vaccine was recommended for universal childhood vaccination at ages 2, 4, and 6 months [92]; however, it was withdrawn within a year [93] due to a temporal association with intussusception [94]. There is a sense that the age of immunization may be critical for association with intussusception, with older infants being more susceptible. This rhesus rotavirus tetravalent vaccine has also been tested in neonates, with a 0-, 2-, 4-month three-dose schedule, where it did not cause fever or other serious adverse events [95]. It appeared to induce rotavirus antibodies adequately in this setting, although with lower magnitude and kinetics than in infants starting at 2 months of age. This vaccine is not under further development, however.

Subsequently, two similar vaccines were developed that appear to be safe and immunogenic. The first, another modified Jennerian approach vaccine, a pentavalent human-bovine reassortant rotavirus vaccine was licensed in the United States in 2006 (RotaTeq). It is a live, oral vaccine that contains five reassortant rotaviruses developed from human and bovine parent rotavirus strains [96]. The parental bovine virus strain, Wistar Calf 3 (WC3), was isolated in 1981 from a calf with diarrhea in Pennsylvania, and then reassortants were made. The REST efficacy trial studied the vaccine in nearly 70,000 infants and found a high level of safety and efficacy against severe disease [97]. This vaccine is administered in a three-dose schedule, at 2, 4, and 6 months of age.

A third live attenuated rotavirus vaccine was licensed in the United States in 2008 for oral administration, which is based on a single attenuated human strain (Rotarix). Five phase III clinical trials were conducted worldwide to assess the safety and efficacy of the monovalent vaccine in support of United States licensure. The biologic license application included data from nearly 75,000 infants [98], and showed safety and efficacy against severe disease using a two-dose schedule, beginning at 2 months of age. The use of this vaccine was temporarily suspended by the FDA for several months during 2010 after it was found that the vaccine contained porcine circovirus type-1 (PCV-1). However, PCV-1 is commonly found in pigs and pork products and is not known to cause illness in humans or animals. Therefore, use of Rotarix was resumed in May 2010.

Current recommendations are that rotavirus vaccines be used for universal immunization during infancy, with care to keep the initiation of the two- or three-dose series at a young age. The ACIP also recommends immunization of premature infants, unless they are still hospitalized (to avoid nosocomial transmission to other vulnerable patients in the hospital).

## *Haemophilus influenzae* Type B (Hib) Vaccine

*H. influenzae* was a major cause of serious invasive bacterial disease before institution of vaccine programs, and there are still many areas of the world where disease occurs because vaccine is not available. The principal life-threatening diseases are meningitis, bacteremia with sepsis, buccal, preseptal and orbital cellulitis, and epiglottitis. Immunity to the disease is conferred by antipolysaccharide polyribosylribitol phosphate (PRP) antibodies directed to the capsular polysaccharide. A purified polysaccharide vaccine was licensed in 1985; however, it was not effective in children less than about 18 months of age because of their inability to mount robust antibody responses to polysaccharides. The vaccine was only marketed for 3 years. Subsequently, Hib polysaccharide-protein conjugate vaccines were developed that are effective in young infants.

The Hib polysaccharide has been successfully conjugated to several proteins, the meningococcal group B outer membrane protein C (vaccine designated PRP-OMPC), tetanospasmin (toxoid of the *C. tetani* neurotoxin, vaccine designated PRP-T), or the mutant diphtheria protein

($CRM_{197}$, vaccine designated HbOC). The vaccines all exhibit a high level of safety and immunogenicity. Hib conjugate vaccine is expensive to manufacture, limiting worldwide implementation, and occasional supply problems have limited full use in the developed world. Nevertheless, the vaccine has virtually eliminated the disease in countries where universal vaccination is used. Furthermore, it has been observed that widespread immunization reduces not only disease but also nasal carriage, resulting in extended benefits due to herd immunity and lack of transmission to even those not vaccinated.

### *Neisseria meningitidis* Vaccines

*N. meningitidis* is also a significant cause of invasive bacterial disease in childhood, causing sepsis and meningitis. Again, antibodies to the capsular polysaccharide mediate protection against invasive disease. The first meningococcal vaccine was a monovalent polysaccharide vaccine first used in the early 1970s. A quadrivalent polysaccharide vaccine has been licensed since 1981, which protects against four subtypes of meningococcus—A, C, Y, and W-135. Children less than 2 years of age do not mount an adequate response to the polysaccharide, so this vaccine is used only in older children. A tetravalent meningococcal conjugate vaccine, also containing the A, C, Y, and W-135 subtypes, has now been developed and was licensed in the United States in 2005. The conjugate is expected to induce more durable immunity in vaccinees. Currently it is licensed for use in persons 2 to 55 years of age, although clinical trials are ongoing to determine the safety in younger populations. Neither the polysaccharide nor the conjugate vaccine protects against subtype B, which causes about one third of all the meningococcus cases in the United States.

## PREMATURE INFANTS

Premature infants are at special risk for many infectious diseases for several reasons. First, if birth occurs before about 32 weeks, very little maternal antibody is transferred to the baby before birth. Second, the physiology of the airways, gastrointestinal tract, and other organ systems is not fully mature, and severe disease is more common on that basis. Third, premature infants are even more immature immunologically than term infants, who themselves mount immune responses to infection that are less robust than those of older children and adults. Therefore, premature infants are an especially vulnerable population who should be the focus of high compliance with vaccination recommendations. Studies reveal, however, that immunizations are not being given in a timely manner to many of these infants [99].

There are specific data on the use of a number of licensed vaccines in premature infants, especially for hepatitis B vaccine. The response of infants weighing less than 2000 g to this vaccine is lower than that of term infants [100]; however, there may be benefit to early vaccination. Current guidelines recommend that the initial vaccine dose be given as usual, but if the infant weighs less than 2 kg on initial immunization, this dose is not considered part of the routine three-dose vaccination series.

### Rotavirus

Rotavirus vaccine should be given to premature infants, if the recommended schedule can be accomplished in a timely manner. In the phase III trials of RotaTeq, vaccine or a placebo was administered to 2070 preterm infants (25 to 36 weeks of gestational age; median: 34 weeks) [97]. The ACIP considers the benefits of rotavirus vaccine vaccination of premature infants to outweigh the theoretical risks of horizontal transmission by shedding. Given this recommendation, premature infants should be immunized with rotavirus vaccine upon discharge from the neonatal intensive care unit if between 6 and 12 weeks of chronologic age.

### Influenza

Vaccinating all household contacts and caregivers of premature infants against seasonal influenza is indicated, as discussed previously. Neonates are not eligible for vaccination themselves.

### TdaP

Again, all close contacts should be up to date on these immunizations, as discussed previously. Mothers should be offered postpartum immunization, if needed.

## REGULATION OF VACCINES AND ADVISORY BODIES

Vaccines are regulated by national governments. The United States Food and Drug Administration's Vaccines and Related Biological Products Advisory Committee (VRBPAC) reviews and approves use of vaccines in the United States. Just because a vaccine is licensed by a regulatory agency, however, does not mean that it will automatically be used in practice. Various advisory boards review the feasibility and appropriateness of implementing vaccination, especially universal vaccination.

The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention provides advice and guidance on effective control of vaccine-preventable diseases in the U.S. civilian population. The ACIP develops written recommendations for routine administration of vaccines to the pediatric and adult populations, and suggests details of vaccination schedules in terms of dosage, frequency, and contraindications. ACIP statements are considered official U.S. federal recommendations for the use of vaccines and immune globulins.

The Committee on Infectious Diseases of the American Academy of Pediatrics (AAP) publishes *The Red Book*, the official publication of the academy containing guidelines pertaining to infectious diseases. It is updated every 2 to 3 years; interim policy updates are issued in the academy's journal. The guidelines from these regulatory and advisory bodies occasionally vary from one another for a time, but in general there is an effort to harmonize recommendations.
